VALEDICTORY.

IN presenting to the profession the fifth and concluding volume of the "SYSTEM OF PRACTICAL MEDICINE BY AMERICAN AUTHORS," the Editor may be permitted to refer briefly to labors which for years have called forth his strenuous endeavors. The original prospectus of the work was issued in 1881. The first volume was published in January, 1885; the second, in May, 1885; the third, in September, 1885; and the fourth, in February, 1886. In view of the delays inevitable in large and complicated literary enterprises, such unusual punctuality reflects credit alike on the zeal of the contributors and the energy and resources of the publishers. The duties of the Editor have been lightened and rendered agreeable by the unvarying courtesy and cordial co-operation of all connected with him in the undertaking; and he has been amply rewarded by the realization of his hopes in the favorable reception accorded to the successive volumes by the profession on both sides of the Atlantic. The plan of the work has been strictly adhered to, and the articles promised have been furnished without exception, although in a very few cases circumstances required a change in the authorship. Special mention is due to Dr. Louis Starr and to Dr. Judson Daland for the very valuable assistance they have rendered.

The only alloy to the pleasure which the Editor has had in the progress of the work has been the removal by death of so many of his distinguished collaborators: such men as Flint, Van Buren, Armor, Bemiss, and Elsberg will long be mourned by the profession.

The number of articles is 185, written by 99 authors, covering, with indexes, about 5600 pages, and throughout its whole extent the original purpose has been kept constantly in view, that the practical character of the work should adapt it specially to the needs of the general practitioner. In conclusion, the Editor feels that it is a subject of congratulation that through the combination of so many leading members of the profession it has been rendered possible to present in this work, for the first time, the entire subject of practical medicine treated in a manner truly representative of the American School.

CONTENTS OF VOLUME V.

DISEASES OF THE NERVOUS SYSTEM.

CONTRIBUTORS TO VOLUME V.

ASHHURST, JOHN, JR., M. D.,

Professor of Clinical Surgery in the University of Pennsylvania.

CONNER, P. S., M. D.,

Professor of Anatomy and Clinical Surgery in the Medical College of Ohio; Professor of Surgery, Dartmouth Medical College; Surgeon to Cincinnati and Good Samaritan Hospitals, Cincinnati.

DAVIS, EDWARD P., A. M., M. D.,

Lecturer on Physiology, Rush Medical College, Chicago, and lately Medical Superintendent of the Presbyterian Hospital, Chicago.

EDES, ROBERT T., M. D.,

Jackson Professor of Clinical Medicine in Harvard University, Boston, Mass.

FOLSOM, CHARLES F., M. D.,

Visiting Physician for Nervous and Renal Diseases, Boston City Hospital; formerly Assistant Professor of Mental Diseases in Harvard University, Boston.

HAMILTON, ALLAN McLANE, M. D.,

Consulting Physician to the New York City Male and Female Insane Asylums; Hudson River State Asylum for the Insane; Consulting Neurologist to Hospital for Ruptured and Crippled; Attending Physician to Hospital for Nervous Diseases; Member of the New York Neurological Society.

HUNT, WILLIAM, M. D.,

Surgeon to the Pennsylvania Hospital, and to the Philadelphia Orthopædic Hospital and Infirmary for Nervous Diseases.

JACOBI, MARY PUTNAM, M. D.,

Professor of Therapeutics at the Women's Medical College, New York.

LEWIS, MORRIS J., M. D.,

Physician to the Episcopal Hospital and to the Children's Hospital; Assistant Physician to the Orthopædic Hospital and Infirmary for Nervous Diseases, Philada.

LLOYD, JAMES HENDRIE, A. M., M. D.,

Instructor in Electro-Therapeutics in the University of Pennsylvania.

LYMAN, HENRY M., A. M., M. D.,

Professor of Physiology and of Diseases of the Nervous System in Rush Medical College, Chicago; Professor of Theory and Practice of Medicine in the Woman's Hospital Medical College, Chicago; one of the Attending Physicians to the Presbyterian Hospital, Chicago, Ill.

MILES, FRANCIS T., M.D.,

Professor of Physiology and Clinical Professor of Diseases of the Nervous System,
University of Maryland, Baltimore.

MILLS, CHARLES K., A.M., M.D.,

Professor of Diseases of the Mind and Nervous System in the Philadelphia Polyclinic and College for Graduates in Medicine; Lecturer on Mental Diseases in the University of Pennsylvania; Neurologist to the Philadelphia Hospital.

MINOT, FRANCIS, M.D.,

Hersey Professor of the Theory and Practice of Physic in Harvard University;
Physician to Massachusetts General Hospital.

MITCHELL, S. WEIR, M.D.,

Member of the National Academy of Sciences; President of the College of Physicians of Philadelphia.

PUTNAM, JAMES J., A.B. (Harv.), M.D. (Harv.),

Physician to Out-patients at the Massachusetts General Hospital; Clinical Instructor at Harvard Medical College.

SCHMIDT, H. D., M.D.,

Pathologist to the Charity Hospital of New Orleans.

SEGUIN, EDWARD C., M.D.,

Clinical Professor of Diseases of the Mind and Nervous System in the College of Physicians and Surgeons, New York City.

SINKLER, WHARTON, M.D.,

Physician to the Philadelphia Orthopædic Hospital, and Infirmary for Nervous Diseases.

SPITZKA, E. C., M.D.,

Consulting Neurologist to the North-eastern Dispensary, and Physician to the Department for Nervous Diseases of the German Poliklinik.

STARR, M. ALLEN, M.D., PH.D.,

Professor of Diseases of the Mind and Nervous System, New York Polyclinic;
Attending Physician to Department of Nervous Diseases, Demilt Dispensary.

WILSON, JAMES C., A.M., M.D.,

Physician to the Philadelphia Hospital, and to the Hospital of the Jefferson College;
President of the Pathological Society of Philadelphia.

WOOD, HORATIO C., M.D., LL.D.,

Clinical Professor of Diseases of the Nervous System and Professor of Materia Medica and Therapeutics in the University of Pennsylvania; Neurologist to the Philadelphia Hospital; Member of the National Academy of Sciences.

DISEASES OF THE NERVOUS SYSTEM.

GENERAL SEMEIOLOGY OF DISEASES OF THE NERVOUS SYSTEM; DATA OF DIAGNOSIS.

By E. C. SEGUIN, M.D.

I. Psychic Symptoms.

ABNORMAL EMOTIONAL STATES.—Emotional manifestations, spontaneous or provoked from without, are, in the civilized adult, held in check directly or indirectly by the will, or by so-called strength of character. Extreme variations are allowed as being within the normal, from the stupidity of the peasant and the impassability of the hero to the sensitiveness and almost unrestrained reactions of the child or of the artist. Each individual must be judged by his own and his racial and family standards in this respect. It is more particularly when the dulness or over-active state observed is in contrast with the subject's habitual demeanor that the condition is called pathological.

Emotional dulness, or the complete absence of any emotional manifestation, may depend upon (1) diminished sensibility to external influences; (2) sluggishness of cerebral action, more especially in the range of sensori-ideal processes, or to general want of intelligence; (3) absorption of the subject's cerebral powers in some special object, real or delusive. The first form is illustrated in various grades of idiocy and backwardness; the second, in fatigue, prostration, and in conditions of dementia; the third is well exemplified in cases of insanity where the patient is devoted to one delusion or dominated by hallucinations (melancholia attonita), in which case the subject may be told the most painful news, insulted most grievously, or threatened fearfully without manifesting grief, anger, or fear. In some instances absolutely no emotional life can be detected.

Emotional exaltation may be due to (1) increased sensibility to external influences; (2) to deficient self-control. The first condition is illustrated in neurasthenic and hysterical subjects and in forms of mania: slight or almost imperceptible provocations call forth reaction, a noise causes fear, a look anger or tears, etc.; the second mechanism is apparent in diseases (dementia paralytica) where the cerebral hemispheres are extensively diseased and the cerebral power lessened (more especially is this the case where the right hemisphere is injured), and in cases of simple debility or asthenia, as when we see a previously mentally strong man shed tears or start most easily in convalescence from acute disease.

It may also be stated, in general terms, that the emotions are manifested in inverse ratio to the subject's mental or volitional power. Psy-

chologically, the emotions are intimately related, on the one hand, with sensory functions, and on the other with more purely mental functions. Anatomically, it is probable that emotions are generated in basal ganglia of the brain (*thalami optici* and *ganglion pontis*), in close association with the sensory areas of the cortex cerebri, while the volitional, inhibitory power is derived from regions of the cortex situated frontad. Clinically, we meet with abnormal emotional states in a great many diseases of the nervous system, more especially in hysteria, neurasthenia, and insanity.

DEPRESSION in the psychic sphere manifests itself by the presence of psychic pain (*psychalgia*), by slowness of emotive reaction and of intellection, and by the predominance of fear, grief, and other negative emotional states. This complex mental state is usually accompanied by corresponding physical symptoms—general debility, reduced muscular strength, slowness of visceral functions, and retarded metamorphosis. The features are relaxed and passive; the posture sluggish, indifferent, or cataleptoid; the animal appetites are reduced. It is seldom that the entire economy does not sympathize with the psychic state. In exceptional cases some emotions are abnormally active, as in *hypochondriasis*; or there may be abnormally active muscular movements, as in *melancholia agitata*. Usually, depression is a part (a fundamental part, however) of a more complex symptom group, as in *hypochondriasis*, *melancholia*, *hysteria*, the prodromal stage of *mania* or *paralytic dementia*, etc.; but sometimes it constitutes a so-called disease—*melancholia sine delirio*. Although depressed subjects often appear indifferent to their surroundings, and react slowly or not at all, it must not be supposed that their emotions are not subjectively active. They are often abnormally so, and psychic hyperæsthesia coexists with *psychalgia*. No anatomical seat can be assigned to the processes which constitute this state and the following; their psychic mechanism is unknown.

EXALTATION, or abnormally great mental activity (including emotions), so-called *psyclampsia*, manifests itself by a pleased or happy subjective state, by increased reaction to external stimuli, by unusually abundant and rapid ideation, and by a corresponding increase of somatic activity, as shown by apparent(?) excess of muscular power, of circulation, of visceral activity, and of the appetites. The entire being, in certain cases, becomes endowed with additional capacity and power. In the mental sphere this over-activity easily passes into incoherence and verbal delirium, while in the physical sphere it may translate itself into violence. Clinically, exaltation may show itself as an independent morbid state, known as *mania sine delirio*. It more commonly appears, with other symptoms, in the shape of ordinary *mania*, of *delirium tremens*, of *dementia paralytica*, etc. Exaltation often follows morbid depression, and these two states sometimes alternate for years (*circular insanity*). Exaltation, even when accompanied by violent muscular action, must not always be considered an evidence of increased nervous power. On the contrary, it is often a result of irritable weakness, and as such indicates a tonic and restorative medication.

ILLUSIONS.—By illusion is meant the result of malinterpretation of an external impression by disordered sensorial or cerebral apparatuses. All of the special senses and the common sensory nerves may be the

media of illusions, but they more commonly manifest themselves in the visual and auditory spheres. A few examples will best illustrate the exact meaning of the term. An insane person mistakes a casual visitor for his brother or father: he fancies that a piece of furniture is a flowering shrub or a threatening animal; another patient will declare that the food in his mouth tastes of a particular poison; still another, having pains in the night, solemnly avers that he has been beaten or cut, etc. A real impression is made upon the centres for vision, taste, and common sensation, but it is wrongly interpreted or appreciated. The exact mechanism of illusions escapes our present means of analysis: the peripheral apparatus or the perceptive centre may be disordered; probably, in most cases, the latter. This is borne out by the fact that in many insane the illusions are in harmony with the delusions present in the mind, and then they are nearly akin to hallucinations. The word illusion is sometimes employed as synonymous of delusion, but this is an abuse of terms to be avoided. Healthy persons are subject to illusions, but the error is quickly corrected by more careful observation by the same sense, or by the use of others. The state of intoxication by cannabis indica (hasheesh) presents numberless illusions of all the senses, together with hallucinations.

HALLUCINATIONS.—By this term is designated the result of the projection into the external world, through nerves of common or special sensations, of formed sensations which arise in a disordered sense-apparatus or nerve-centre; or, in more popular language, it may be said to mean the perception of non-existent objects or impressions, creations of the imagination. Examples: Disease (sclerosis) of the posterior columns of the spinal cord irritates the roots of the sensory nerves, the result being pain at the periphery in the parts connected with the affected segment of the cord. So objective and real do these peripheral pains seem that if the patient's mind be weakened he may assert that they are due to his being beaten, stabbed, or bitten by some one or by an animal. After amputation, the absent member is long perceived by the subject, often with startling distinctness, and even after the sensation has passed away it may be brought back by faradizing the nerve-trunks above the stump. The patient may hear voices, music, or simple sounds when in reality there is silence, or he may be surrounded by imaginary images or plagued by hallucinatory smells and tastes. Hallucinations may also arise in the distribution of optic nerves.

Besides common hallucinations with their seeming reality and objectivity, we admit others which are less vivid, which do not startle or frighten the subject, and which are simply the outward projections of the patient's own thoughts (delusions). The subject of persecution by imaginary enemies may see around him the faces of his pursuers with appropriate expressions, or hears their insulting or threatening remarks, as outward plastic reproductions of his thoughts; but the patient himself recognizes the want of actual objectivity and clearness in these images. These we call, after Baillarger, psychic hallucinations or pseudo-hallucinations. Similar phenomena are observed in some sane persons under excitement and betwixt sleep and waking.

The mechanism of hallucinations is partly understood, and may be stated as follows: In some few cases a real disorder or defect in the

peripheral sense-organ may give rise to false projections; for example, a tinnitus may become transformed into a distinct voice, a scotoma may be the starting-point of false pictures of a man or animal. The simpler hallucinations of pain, cutaneous, muscular, and visceral sensations may originate in irritation of the nerve-trunks (as where the nerves of an arm-stump are faradized and the patient feels his hand with fingers in motion). But the general or common genesis of hallucinations is in disordered states of nerve-centres, those for common sensations and the special centres or cortical areas in the brain. Thus, a morbid irritation of the cortical visual area or sphere will give rise to abundant hallucinations of sight; irritation of the auditory sphere to hallucinations of hearing, as sounds and voices, etc. It must be borne in mind that, however pathological hallucinations may be, they arise from the operation of a fundamental physiological law. In health we constantly refer our sensations or transfer them into the external world, thus creating for ourselves the non-Ego. All terminal sensory nerve-endings receive only elementary impressions or impulses from external agencies, and these are perceived and conceived as images, formed sounds, etc. in the appropriate cortical centres; then by the law of reference of sensations these elaborated, idealized conceptions or pictures are thrown outward again and contemplated as objective. In this physiological mechanism lies the kernel of truth which is included in idealism.

Hallucinations may occur without derangement of mind or impairment of judgment. Many instances are on record of transient or permanent hallucinations of various senses in perfectly healthy persons who were fully aware of the unreal character of what they saw or heard. Being of sound mind, they were able to make the necessary correction by reasoning or by the use of other senses. In very many forms of insanity hallucinations are prominent, though they also occur in quasi-sane conditions, as in hypochondriasis, hasheesh, belladonna, and opium intoxication, the stage between sleeping and waking, etc. As long as the subject is able to correct the false projections by reason or by the use of other senses he is considered sane.

Hallucinations are sometimes the cause of acts by the insane, some of them violent and even murderous actions. Hallucinations of sight and hearing are especially prone to lead to assaults, murders, etc. The occurrence for any length of time of acoustic hallucinations in insanity is accounted of bad prognosis.

DELUSIONS are synonymous, in a popular way, with false beliefs. Thus, we often speak of eccentric opinions, of fanatical or extravagant creeds, as delusions. In a certain sense probably all mankind cherish innumerable delusions. In a strictly medical and medico-legal sense, however, the term is applied only to false beliefs in respect to clearly-established, indisputable facts. Thus, a man who believes in Spiritualism or even in metempsychosis, or in the divinity of a certain personage, is not medically deluded; whereas, one who believes that a bare court is a flowering garden or that he himself is divine is deluded. The essential element in the conception of delusion is belief or conviction on the patient's part; and that is why delusions mean that the psychic functions are deeply and seriously impaired. Delusions may be conveniently divided into ideal and sensorial.

(a) Ideal delusions are false ideas or concepts arising more or less spontaneously, or by morbid association in the subject's mind. For example: he believes that he is a god, that he has millions of money, that his soul is lost, that he has a thousand children, etc. Many of the delirious ideas experienced by insane patients are delusions, and so to a certain extent (subject to temporary corrections by reasoning and demonstration) are the notions of hypochondriacs about their health.

(b) Sensorial delusions are such as are founded upon illusions and hallucinations. The moment a subject is convinced of the reality of an illusion or hallucination, believes in its actuality, he is said to have a delusion. The change from illusion and hallucination to the state of sensorial delusion indicates a deeper psychic alteration—a failure of critical capacity or judgment. Examples: A man imagines the stump of a tree in front of him to be a human being, but by reasoning, by closer visual inspection, or by palpation he concludes that it is a tree, after all; this is a simple illusion. If he persists, in spite of argument and demonstration, in his assertion that the stump is a human being, he is said to have a delusion or to be deluded. If a person sees wholly imaginary flowers or hears imaginary voices, as long as he is capable of recognizing the falsity or want of actuality of these images or sounds he has a simple hallucination; if he ceases to make the necessary correction, and believes the flowers and voices to really exist, he has sensorial delusions. It should be borne in mind that sane persons may have hallucinations, and that some insane have no sensorial delusions; also, that some insane are capable of correcting, for a time at least or when closely questioned, their illusions and hallucinations. Apart from these exceptional conditions, delusions, sensorial and ideal, are most important symptoms of insanity. We also meet temporary delusions in toxic conditions (from Indian hemp, alcohol, etc.) and in the delirium of acute general disease, of low febrile states, starvation, etc. Delusions are sometimes named in groups, according to the prevailing type of mental action; then, we have exalted delusions, in which the false notions and beliefs are rose-colored or extremely exaggerated (as in paralytic dementia, etc.). Again, we speak of delusions of persecutions, where the patient fancies himself pursued, maltreated, insulted, or where he insanely follows up and persecutes others. Such classification is useful for purposes of clinical and psychical study.

Imperative conceptions or controlling morbid ideas and desires are ideal delusions presenting certain peculiarities; one of which is that of growth by accretion and assimilation by a sort of false logic and grotesque analogical reasoning, until from a mere fancy or notion the growth invades and governs the entire subjective life of the subject.

VIOLENCE is a complex symptom always deserving of study and psychological analysis. It may present itself as an increase of a naturally bad disposition or as a wholly new exhibition of irritability and temper. Beyond these limits it may assume the shape of abusive and foul language (not before employed by the subject), or of physical acts of a destructive or dangerous character. Viewing the condition from a psychological standpoint, we should endeavor to distinguish between merely impulsive or animal violence due to over-activity of the emotional state or to a loss of self-control (cortical inhibition), and quasi-deliberate acts due either to special delusions or to delirium. Abnormal irritability, or increase in an

originally bad temper, is met with in hysteria, neurasthenia, and partial dementia. Masturbators and epileptics frequently exhibit this condition. In a state less pathological, from mere fatigue or overwork, irritability may temporarily show itself as a result of reduced cortical energy; and in such cases rest, a cup of tea or coffee, alcohol, or even ordinary food, restores good-nature and equanimity as by magic. In little children bad temper is a frequent precursor of illness, more especially of cerebral disease. Greater degrees of violence in speech and acts are met with in hysteria, neurasthenia, and in many forms of insanity, in the guise of exaggerations of animal propensities, to make a noise, break objects, injure persons in an aimless general way. Voluntary or quasi-voluntary acts of violence are those which are done under the influence of hallucinations, delusions, or of delirious ideas, usually by insane patients. The delirium of acute or inflammatory disease or of the typhous state is rarely active, although pericarditis sometimes gives rise to very violent delirium, and the mild delirium with picking and gesticulating of pneumonia, typhoid fever, etc. may sometimes simulate mania. In general terms, the words and acts of patients represent the ideas passing through their minds in a rapid confused way, much as in dreams. Violence done under the influence of clearly-defined hallucinations and delusions is most dangerous, because it is executed with apparent deliberation and volition. Thus, a man laboring under hallucinations of hearing, fancying himself insulted, may turn in the street and strike or shoot some one near him, the supposed author of the insult. An epileptic falls in a partial attack or has epileptic vertigo; as a part of the seizure there is a dream-like scene of assault, actual or threatened, upon him, and on rising from the ground, or after the momentary vertigo the patient, acting in accordance with the demands of the dream-like scene, makes an onslaught upon those near him or smashes furniture, etc. Seeing such acts, without knowing their genesis, one is liable to consider them normally deliberate and malicious. On recovering consciousness (which may not be for several hours or days) the epileptic patient appears utterly oblivious of his actions, and is much astonished to learn what he has done. In many cases of insanity violent acts are done through a similar psychic mechanism—*i. e.* through the domination of delusions. Delusions often give rise to what may be termed negative violence—resistance to personal care, treatment, giving of food, etc. This is exemplified in acute melancholia, with overpowering fears of all kinds and terrorizing hallucinations of sight and hearing. The patients crowd in corners or sit curled up, and resist with all their might whatever is done for them, even striking and biting the attendants.

Therapeutically, the question of physical restraint or non-restraint in the management of violence might be discussed here, but the question is one which can be much better considered in connection with the general treatment of insanity, and the reader is consequently referred for information to the article on that subject.

DELIRIUM is a term which has been so variously applied that a brief definition of it is wellnigh impossible. Illogical or unreasoning and incoherent thoughts expressed in words and acts may suffice to give a general idea of the condition. Extreme applications of the term are, for example, to say that in a case of extreme dementia the rambling, disconnected talk is delirium, or that in certain forms of monomania the expres-

sion of the patient's peculiar delusion is delirium. It seems to us that there should be a certain degree of activity in the production of morbid ideas, with confusion in their expression, to justify the use of the term delirium. Again, in some instances the delirious talking and acting are only the reflex of abundant hallucinations of various senses which beset the patient. In some other respects the term delirium is applied in several distinct ways: first, in a substantive form as a designation for the incoherent words and acts of a patient. Usually, it is then put in the plural form of deliria. Thus we have the more or less highly organized, fixed or changeable deliria of monomania, chronic mania, melancholia, parietic dementia, etc., and the confused and evanescent deliria of acute general diseases, intoxications, and many forms of insanity. In short, we may speak of a sick person's deliria as we would of a normal person's thoughts; or in still more elementary analysis deliria are abnormal or insane thoughts and corresponding action. Second, delirium is used adjectively as designating certain diseases—*e. g.* delirium tremens, delirium a potu, acute delirium, delirium of acute diseases, etc. The seat of the psychic processes which go to make delirium is undoubtedly the cerebral cortex. This view is supported partly by the clinical consideration that delirium bears a certain relation to the psychic development of the subject. Thus, we see in children and in the higher animals rudimentary or fragmentary deliria; in advanced age the delirium is feeble and well-nigh absent; while in ordinary adults with well-developed cerebration deliria are abundant and varied. From pathological anatomy we learn that deliria become simplified and subside in proportion as the cerebral cortex becomes more and more damaged by effusions, by pressure effects, or by degenerative changes. As to the relation between special histological pathological changes, our knowledge is small and to a certain extent paradoxical. Thus, it is universally admitted that delirium may be due either to hyperæmia or to anæmia of the brain. The delirium of alcoholic or cannabis intoxication may be fairly assumed to be of sthenic or hyperæmic origin, either by the nervous elements themselves being in an exalted state of irritability, or because an increase in the circulation of arterial blood in the brain leads to greater activity of the cellular elements. Again, delirium appears in conditions of general or cerebral anæmia, as in starvation, after prolonged fever, after the withdrawal of customary stimuli, etc. These views are confirmed by the fact that some deliria cease upon the administration of sedatives and narcotics, while others are relieved and cured by rest, stimulants, and food. On the other hand, a large class of deliria, as exhibited in the insane, escape pathological analysis; for example, the delirious conceptions of monomania occurring in apparent somatic health and without well-marked symptoms of cerebral disease. We are much in the dark as to what the processes may be by which delusional notions grow in the subjective life and manifest themselves outwardly as deliria. It is probable that in such cases there is no material lesion (appreciable to our present means of research), but a morbid dynamic condition, false reactions, abnormal centripetal and centrifugal associations in the psychic mechanism, with or without inherited bias. The diagnosis of delirium as a symptom is usually easy, but it is a task of no small difficulty to determine its pathological associations in a given case, and to draw from this study correct therapeutic indications.

A careful review of the antecedent circumstances, of the patient's actual somatic condition, more especially as regards hæmic states and vaso-motor action, is indispensable.

LOSS OF CONSCIOUSNESS, COMA.—Suspension of all sensibility, general and special, with loss of all strictly cerebral (cortical) reflexes, is met with in many pathological states. Its physiology or mode of production is unknown, but there are good reasons for believing that the lesion, vascular or organic, affects chiefly the cortical substance of the hemispheres. Its clearest manifestation, clinically, is after depressed fracture of the skull or after concussion of the brain, without or with abundant meningeal hemorrhage. In the last case unconsciousness or coma appears as an exaggeration of drowsiness or stupor; after a fall the patient may be able to walk into the hospital, but soon becomes drowsy, then stupid, and lastly completely insensible. In the first case, that of depressed fracture of the skull, the raising of the depressed bone is often followed immediately by return of consciousness; the patient seems to wake as from a deep sleep. In medical practice there are many analogous conditions of abnormal pressure causing coma, as in meningitis, cerebral abscess, hemorrhage, embolism of cerebral vessels, etc. Long-continued or fatal coma may be caused by general morbid states, as uræmia, acetonæmia, surgical hemorrhage, intoxication by narcotics, alcohol, ether, etc., and by asphyxia. Momentary loss of consciousness is induced in the various forms of epilepsy, lasting from a fraction of a second (so short as not to interrupt walking) to one or two minutes, followed by the more prolonged coma of the asphyxial stage. Temporary unconsciousness is also caused by physical or moral shock, but in many such cases the heart is primarily at fault, and the condition is termed syncope. Although in practice it is most important to distinguish syncope from more strictly cerebral coma, yet it must be admitted (and such admission is important for therapeutics) that in both categories of cases anæmia of the brain (cerebral cortex) is the essential factor or immediate cause of suspension of consciousness. This view of the pathology of coma is borne out by the fact that the condition may be produced at will, experimentally or therapeutically, by compression of both carotid arteries. It may be well to mention here the pseudo-coma of hysteria. In these cases consciousness is really present, as shown by responses to violent cutaneous irritations (faradic brush), by quivering of the closed eyelids and resistance to attempts to open them, by vascular or muscular movements evoked by remarks of a flattering or abusive nature made in the patient's hearing, and by cessation of the condition after complete closure of the nose and mouth for forty-five seconds or one minute (asphyxia). In the typically unconscious state, as in cases of fracture of the skull or of intracranial pressure by exudations, clots, tumors, etc., there are several objective symptoms to be noted. The pupils are usually dilated and immovable (exceptions chiefly in narcotic poisoning); the pulse is reduced in frequency and retarded; it is sometimes full and bounding, or in other cases feeble and irregular. The breathing is often slow and irregular; the patient fills out his cheeks and puffs (smokes the pipe); sometimes the Cheyne-Stokes type of respiration is observed. In hysterical or hypnotic impairment of consciousness these important symptoms are absent: the patient seems simply asleep. Although coma is, strictly speaking, a

symptom, it so often appears as the leading one of a group that it deserves study almost as a disease. Indeed, there are few more difficult problems for the physician than the case of a comatose subject without a good history of the preceding condition, causes, etc. It is impossible here to consider all the possibilities of this problem in diagnosis;¹ we can only state the chief and most probable pathological conditions which may cause coma.

(1) The patient may be epileptic. The following signs of a past convulsive attack should be sought for: a bitten tongue, fleabite-like ecchymoses on the face, neck, and chest, saliva about the face and neck, evidences of micturition or of seminal emission in the clothing, etc. There is usually a small rise of temperature after a single fit, and consciousness soon returns without assistance, or a second seizure appears.

(2) The patient may be suffering from surgical cerebral compression or concussion. Signs of injury about the head or other parts of the body, oozing of blood or sero-sanguinolent fluid from the ears and nose, will sometimes clear up the diagnosis. Especially suggestive of meningeal hemorrhage is a gradually increasing stupor without distinct hemiplegia.

(3) The coma may be uræmic. In some cases anasarca and slow pulse point at once to this pathological condition. In all comatose cases without history the urine should be drawn with a catheter for testing, and signs of various forms of Bright's disease may be detected. The ophthalmoscope (easily used in comatose subjects) may yield most valuable indications by revealing retinitis albuminurica or neuro-retinitis.

(4) The patient may be under the effects of a clot in the brain or of acute softening of a considerable part of the organ. Hemiplegia with conjugate deviation of the eyes and head is usually present, the head and eyes turning away from the paralyzed side, the patient looking, as it were, toward the lesion. A latent hemiplegic state may sometimes be determined by one-sided redness of the buttock, and by a slight difference of temperature between the two hands (paralyzed side warmer). The general temperature of the body (measured preferably in the vagina or rectum) exhibits a marked rise. After cerebral hemorrhage there is, according to Charcot and Bourneville, a fall below the normal during the first hour, followed by a steady rise to 106° or 108° F. at death in severe cases. After embolism or thrombosis, causing softening, the rise of temperature is less in extent and not as regularly progressive.

(5) The subject may be simply drunk or poisoned by alcohol. In such a case the patient may usually be roused momentarily by loud speaking, shaking, or by painful impression; the breath is alcoholic; the cerebral temperature subnormal or normal. The urine must be tested for alcohol.² It must not be forgotten that on the one hand intoxicated persons are most prone to falls causing fracture of the skull or concussion, and on the other hand that the early stage of coma from meningeal hemorrhage resembles narcosis.

(6) The coma of congestive or malignant malarial fever is to be distin-

¹ An able attempt at the differential diagnosis of comatose cases, by J. Hughlings-Jackson, will be found in *Reynolds's System of Medicine*, Am. ed., 1879, vol. i. p. 920.

² Anstie's Test.—A test solution is made by dissolving one part of bichromate of potassium in three hundred parts by weight of strong sulphuric acid. The urine is to be added drop by drop to the solution. If a bright emerald-green color suddenly results from this manipulation, it signifies that there is a toxic amount of alcohol in the urine.

guished mainly by the absence of physical or paralytic symptoms, coinciding with a high rectal temperature. The spleen is often enlarged. Some would add that *Bacillus malarie* and pigment might be found in the splenic blood, withdrawn by a long, fine needle.

(7) Toxic narcosis, from opiates, morphia, chloral, etc., are often difficult of diagnosis, except that from opiates and morphia, in which extremely slow respiration and contracted pupils, with lowered temperature, point at once to the cause.

In studying cases of coma all the above-enumerated symptoms should be considered as of great negative or positive value: often the diagnosis is only made by exclusion. The Cheyne-Stokes respiration, pupillary variations, differences in pulse-rate and volume, are present in such varied conditions, irrespective of the nature of the lesion, as to render them of minor value in differential diagnosis.

DOUBLE CONSCIOUSNESS is a rare condition, in which the subject appears to have separate forms or phases of consciousness, one normal, the other morbid. This occurs in hypnotic and somnambulist states, probably also in certain cases of insanity and epilepsy. The current of normal consciousness is suddenly broken; the patient enters into the second or abnormal state, in which he acts, writes, speaks, moves about with seeming consciousness; but after a variable time a return to normal consciousness reveals a break in the continuity of the memory: the patient has no recollection whatever of what he did or said in the morbid period. In the hypnotic state subjects may show increased power of perception, and are strangely susceptible to suggestions or guidance by the experimenter. In a second attack the patient often refers back to the first, and does things in continuation or repetition of what he previously did, apparently taking up the same line of thought and action. The morbid states, long or short, are joined together by memory, but are wholly unknown in the normally conscious states. In other words, the patient leads two (or three, according to a few observations) separate lives, each one forming a chain of interrupted conscious states. In epilepsy we observe remarkable breaks in normal consciousness: the patient goes through certain acts or walks a distance or commits a crime in a dream-like state, and suddenly, after the lapse of a few minutes, hours, or days, becomes normally conscious and has no recollection of what he did with such apparent system and purpose during the seizure. It might, perhaps, be as well to classify these phenomena under the head of amnesia. A case is on record where a man travelled, seeming normal to fellow-travellers, from Paris to India, and who was immensely astonished on coming to himself (return to common consciousness) in Calcutta. Many murders have been committed with apparent design and with skill by epileptics, who upon awaking from their dream-like state were inexpressibly horrified to hear of their misdeeds.

AMNESIA, or loss of memory, may vary in degree from the occasional failure to remember which is allowed as normal, to the absolute extinction of all mental impressions or pictures. This word and the expression memory are here used in a restricted sense, reference being had only to purely intellectual and sensorial acts related to intellection. If we take the general or biological sense of the term memory as meaning the retention of all kinds of residua from centripetal impressions and of motor

centrifugal impulses, including common sensory and visual impressions, special sense impressions, all unconsciously received impressions, emotional, intellectual, and motor residua, we should consider amnesia in a correspondingly general way. This, however proper for a physiological study, would be far too complex and premature for an introduction to practical medicine. Recognizing memory, therefore, as a universal organic attribute—a capacity to retain impressions—we will treat of it only in the commonly-accepted sense referred to supra.

Failure of memory may be real or apparent. In the latter sense amnesia is induced by diversion of the attention into a channel different from that in which the line of inquiry is conducted. A normal example of this is seen in the state known as preoccupation, where a person intent upon a certain thought or action forgets who is about him, where he is, and if asked questions fails to answer or answers incorrectly. In pathological states, as in acute curable insanity, apparent loss of memory is often caused by the domination of an emotion or of delusions. In both cases, if the subject can be roused or brought to himself, he remembers all that we inquire about and is amused at his previous false answers or silence. Real amnesia consists in the actual blotting out of recollections or residua in a partial or general manner, for a time or permanently. These differences serve as the basis of a complicated subdivision of amnesia which it is not necessary to fully reproduce here.

Temporary partial amnesia is a variety which is frequently observed in normal persons, even the most gifted. A word or fact escapes us, seems wholly lost for a few minutes, hours, or days; the more we strive to recall it, the less we succeed; yet later, when not sought for, the fact or word appears in our consciousness as if spontaneously, but more probably by some effect of the law of association. Such partial and momentary forgetfulness may assume proportions which render it pathological. What is known as transitory aphasia may be classed in this group. In a few minutes or hours a person without apoplectic, epileptic, or paralytic phenomena loses all power to express his thoughts by speaking or writing; there is verbal amnesia and agraphia. The subject is conscious of his condition and of the wholly futile or incorrect attempts he makes to communicate with others.

Temporary complete amnesia is almost equivalent to loss of consciousness, yet not strictly so. For example, after a sharp blow upon the head a person may perform complicated acts, reply to questions, and apparently act normally, yet after a variable time he will declare that he remembers absolutely nothing of the injury and what he did or said for hours or days afterward. The same phenomenon is observed in the course of psychoses, neuroses (epilepsy), in some acute diseases, and in certain states of intoxication.

Permanent partial amnesia occurs in states of dementia, such as senile dementia, paralytic dementia, and in certain cases of aphasia. Great gaps exist in the patient's memory; some things are well recalled, others wholly and for ever effaced. The psychological law governing the failure of memory in these cases is that the earliest and strongest impressions survive, while recent and less forcible (*i. e.* less interesting) ones are lost. Substantives or names are especially liable to obliteration, as are also many of the delicate residua which lie at the basis of the subject's ethical conceptions and acts.

Permanent complete amnesia is observed at the end of degenerative cerebral diseases, as organic dementia, whether of the form termed secondary or that designated as paralytic. Sometimes after acute general diseases the memory may be a perfect blank for a considerable length of time, and education has to be repeated. Memory may be so completely absent that cases are known in which the patient gave a fresh greeting to the asylum physician every two or three minutes indefinitely, as if each were a first meeting. Momentary perception and automatic (reflex) response are there, but no impression is made; there is no residuum left in the cortical centres. In these cases amnesia is accompanied by degeneration of the visual, auditory, etc. cortical areas or centres.

An interesting form of amnesia, not generally recognized as such, is the loss of acquired skill in muscular movements, such as are necessary for writing, for using tools, and for doing various delicate professional movements. Here the motor residua acquired by laborious education or training are gradually lost without actual paralysis or ataxia. This variety is exquisitely illustrated by certain cases of dementia paralytica where long before marked intellectual symptoms occur there is loss of skill in mechanical arts and in handwriting.

In testing a subject's memory due attention should be paid to the law of the survival of older and more interesting residua, as well as to the power of the law of association. Such questions should be asked as pertain to recent events in the patient's experience, and about matters which are not closely related logically. A patient who might tell us nearly all about his early personal experiences, his business and family relations, incidents of his childhood, etc., would fail to remember what he had for breakfast, what he did the day before, etc.

The physiological cause of real amnesia is impairment in the vitality (nutrition) of ganglion-cells in the various cerebral sensory areas or centres, and of the motor area as well (motor residua). In cases of transitory amnesia we suppose this to be due to the action of toxic agents, to anæmia, and impaired molecular or chemical nutrition, as after acute diseases, in extreme debility, in psychoses, etc. In cases of terminal permanent dementia, autopsies afford us evidence of degeneration and disappearance of ganglion-cells: we find granular and fatty pigmentation, atrophy, calcareous degeneration of these bodies, thickening and shrinkage of the neuroglia, and degenerative changes in blood-vessels. Doubtless degeneration or destruction of association fasciculi of nerve-fibres in the cortex cerebri or in the white substance plays a considerable part in the production of permanent amnesia, but we are as yet unable to give a clear demonstration of this. Theoretically, we may admit an organic loss of memory with the following conditions of the brain: (1) diseased perceptive (sensory) centres or motor area with normal association fasciculi; (2) normal perceptive centres and motor area with degenerate or broken association fasciculi, connecting these parts with one another and with the more strictly ideational or expressive (centrifugal) areas and parts of the brain and spinal cord.

Amnesia—or, more properly speaking, dulness of perception and feebleness of retention of residua—occurs as a strictly congenital condition from imperfect cerebral development, or a little later in life from infantile diseases, constituting one of the aspects of idiocy.

WORD-DEAFNESS is a special morbid psycho-sensory state in which the sounds of language lose their significance for the patient. The sense of hearing is preserved for common sounds, and even music in certain cases; words are heard, but not understood. A patient of mine having this symptom used to say, "If I go to a lecture or hear a sermon, I hear the speaker, but what he says is all Greek to me." On the other hand, this gentleman could go to a concert and understand the musical notes. This condition occurs as a part of the symptom-group aphasia, or it may show itself independently in the course of limited cerebral cortical degenerations. The lesion causing word-deafness is usually found in the left hemisphere, in the first and second temporal gyri, or it may be in the inferior parietal lobule and gyrus supra-marginalis, penetrating deeply enough to injure fasciculi going into the temporal lobe. It would appear, from the evidence now before us, that the centre for psychic hearing is in the caudo-dorsal part of the temporal lobe.

WORD-BLINDNESS, or alexia, is another special morbid psycho-sensory state, in which the visible signs of language lose their significance for the patient. Usually there is no impairment of sight; the patient can see the letters and words as objects, but he cannot read them at all, or must do so letter by letter. Even numerals and pictures of objects in some cases become unintelligible. In testing for this condition a possible confusion with verbal amnesia must not be forgotten. In such a case the patient knows the word or object, but cannot name it; usually he can, however, inform us by signs or indirect expressions that he takes proper cognizance of the object. Alexia is present in a certain proportion of cases of aphasia, and it may be complicated with lateral hemianopia. The exact seat of the lesion producing alexia is at present unknown. Theoretically, however, we must place it in the course of paths from the cortical visual area (cuneus and adjacent gyri) to the general speech-centre. Psychic blindness for objects in general (soul-blindness of the Germans) is now quite conclusively proved to be due to degeneration of both occipital lobes, more especially their mesal gyri, where the visual centres are. This psycho-sensory state, with the accompanying cortical changes, has been demonstrated in cases of dementia paralytica.

APHASIA, or loss of the faculty of language, is so important a symptom as to deserve elaborate consideration in a separate article of this volume; and to it the reader is referred. Suffice it here to state that aphasia may be classified into three forms: (1) Sensory aphasia, in which there is primary disorder of the psycho-sensory (perceptive or centripetal) part of the complex central mechanism for speech; (2) Motor aphasia (including ataxic aphasia), in which the primary lesion affects the motor (expressive or centrifugal) parts of the mechanism; (3) Amnesic aphasia, in which loss of memory (effacement of residua) of words and signs is the prime condition.

II. Sensory Symptoms.

HYPERÆSTHESIA is a condition of exalted excitability in the various parts of the sensory apparatus: terminal nervous organs, nerve-trunks, central gray matter. We may admit such a state as existing independ-

ently of consciousness, as where a lesion cuts off communication between the perceptive cerebral centres and the periphery, but in practice we consider only conscious hyperæsthesia. In this state the subject may be able to perceive (feel) slighter impacts than would affect a normal individual, or he receives an exaggerated, usually unpleasant, impression from ordinary excitations. It may also be said that hyperæsthesia exists as a purely subjective state, psycho-sensory hyperæsthesia, without external mechanical excitations.

(a) Hyperæsthesia of common tactile sensibility in the skin and mucous membranes is frequent. The least touch is felt with unpleasant acuteness and causes unusual reactions of a reflex order; frequently, but not necessarily always, a sensation of pain is produced at the same time. It has been claimed that in certain cases the points of the æsthesiometer could be perceived (distinguished as two points) at smaller distances than the average normal, but I have never been able to demonstrate this to my satisfaction. The simplest form of tactile hyperæsthesia is met with in persons of a highly nervous organization, in those under the influence of strong emotions, in the hypnotic state, and while intoxicated. The common pathological conditions in which increased sensibility is found are meningitis (cerebral and spinal), hydrophobia, tetanus, neuritis, dermatitis, hysteria, and spinal irritation; also in connection with inflammations and traumatism.

(b) Hyperalgesia, often coinciding with (a), is that condition in which pain is produced by excitations so slight that they would not affect a healthy nervous apparatus: it is commonly designated as tenderness. Acute and dull, superficial and deep tenderness should be sought for and distinguished, as having different values in diagnosis. A type of deep tenderness is that found upon pressing steadily upon a diseased nerve-trunk. Acute superficial hyperalgesia is best studied in cases of trigeminal neuralgia and spinal irritation. Occasionally, universal hyperalgesia is met with, usually in hysterical women.

(c) Hyperæsthesia to thermal impressions is ordinarily shown with reference to cold. In cases of neuralgia or neuritis cold is felt excessively and painfully; in some cases of posterior spinal sclerosis there is the greatest dread of draughts of cold air, and patients protect their legs in an extraordinary manner.

(d) Hyperæsthesia of the muscular sense.¹ The special sensations or notions of muscular states and activities which we possess may be considerably exalted, as shown by greater delicacy and rapidity of movements, and by the abnormally acute way in which perceptions of form and dimensions are obtained by the subject without assistance from other senses. Examples of this condition are met with in hysteria and hypnotism.

(e) Visceral hyperæsthesia is chiefly shown by abnormal consciousness of the presence and action of an organ. Visceral pain usually accompanies this, and is the more prominent symptom.

(f) Increased reflex actions (emotional, motor, vaso-motor, and secrete-

¹ This term is employed as clinically sufficient. It is impossible in this article to enter into a consideration of the various theories held with reference to the function in question, whether it be psycho-motor, psycho-sensory, or a true muscular sensibility. It certainly differs much from the various forms of common sensibility, and has special paths.

tory) rarely fail to accompany hyperæsthesia in its various forms. In the hypnotic exaltation of muscular sense remarkable psychic effects may be induced, partly in a reflex way, but perhaps chiefly through the law of association.

PARÆSTHESIÆ are sensations which arise centrally in nerve-fibres or nervous centres, and are projected outward and referred to the periphery or surface by consciousness, in obedience to the general law of outward projection of sensations in the Ego. They may be produced by external agencies or arise centrally without demonstrable cause. Their number and variety are very great, varying somewhat with the descriptive powers and self-consciousness of the patient, the chief being pain, formication, numbness, coldness and heat, constriction and distension, malposition, imaginary movements, etc. etc.

(a) Pain, the most distinct and frequent of paræsthesiæ, is by most authors classed as a hyperæsthesia, yet a careful analysis will show the difference. Pain and hyperæsthesia often coexist and are inseparable, yet in a large proportion of cases of nervous diseases the former sensation occurs independently, sometimes in regions where absolute anæsthesia exists (anæsthesia dolorosa), and even apparently in lost parts (neuralgia after amputations). We are consequently justified in considering most pains as paræsthesiæ. Pain assumes many forms, some real and typical, others as various as the lively imagination of nervous patients can make them. Thus we have sharp, cutting, darting pains in neuralgia, posterior spinal sclerosis, etc.; aching, throbbing, pounding pains in cephalalgia, inflammatory and traumatic conditions; boring, crushing, distending, constricting, burning pains, etc. etc. In some cases the sensation is only semi-painful, and more akin to paræsthesia (neuritis, parenchymatous lesions).

(b) Numbness, prickling, and formication usually coincide. They may easily be produced experimentally by pressure upon a nerve-trunk or by the exhibition of aconitia, so that any one may study these sensations for himself. By taking one-fiftieth of a grain of Duquesnel's crystallized aconitia the experimenter will soon find himself the possessor of intense subjective sensations of prickling, numbness, vibrations, and cold, lasting several hours. He will be able to satisfy himself that though the fingertips feel numb, as if there was a coating or layer of something interposed between the skin and objects, he can distinguish tactile perceptions very well. In the more serious experiment of compression of a nerve-trunk a most interesting succession of phenomena will be observed: the first effects of pressure are various paræsthesiæ in the parts supplied by the nerve; then these sensations (prickling, numbness, swelling, vibration, heat, and cold) cease; paralysis and anæsthesia occur. If the compression be now interrupted, after a few moments the paræsthesiæ reappear, more intensely, as a rule, and as they gradually fade a normal state of sensibility is re-established. By making such experiments it is easy to convince one's self that anæsthesia and numbness are different conditions: indeed, during the stage of recovery from nerve-pressure distinct hyperæsthesia may be demonstrated. These results throw much light on the origin and diagnostic value of paræsthesiæ as expressions of irritation, central or neural, of nervous elements. At the same time, in practice, we occasionally meet with slight dulness of tactile sensibility in numb

parts. Another point to be remembered is that while patients usually complain loudly of paræsthesiæ, they are sometimes wholly unaware of anæsthesia (hysterical analgesia, for example); therefore sensibility should be tested even if the patient does not mention sensory disturbances.

Numbness, formication, etc. occur in a vast number of nervous affections—in cerebral and spinal organic lesions, in neuritis, in toxic conditions, and in neuroses. The distribution of paræsthesiæ is a valuable index to the seat of the lesion.

(e) Cutaneous itching and prickling may occur independently of any other skin lesion, constituting true or nervous prurigo. This may be universal and last for years.

(d) Paræsthesiæ of pressure are felt either as expansive or constrictive. The part appears swollen to consciousness, or it seems to be tightly compressed. Both these sensations are often felt about the head in a variety of pathological states, and an absurd and dangerous fashion has arisen of looking upon a sense of fulness in the head as indicative of hyperæmia. The sense of constriction may show itself around one toe, a leg, the trunk, around the neck, etc.; it may be narrow, like a cord, or broad and extensive, like a stocking or corset. Sometimes it is localized, and likened to the grasp of a hand or a spot-pressure. Not infrequently, especially in cases of paraplegia, the sensation of pressure is combined with subjective cold, the legs feeling as if tightly encased in ice.

(e) Subjective sensations of heat and cold are often of the strongest kind, and are very distressing. A part whose real objective temperature is normal may appear to the patient's consciousness as icy cold or burning hot, even to the degree of apparent contact of fire (causalgia of Mitchell). We observe such sensations in posterior spinal sclerosis, myelitis, neuritis, injuries to nerves. In some functional cases complaint is made of patches of hot or cold skin, not relieved by cold or heat.

(f) Odd sensations, such as rolling or longitudinal motion of something under the skin, general or local throbbing, coition movements, are described, especially in functional or hysteroid cases.

(g) Sensations of hunger, thirst, dyspnœa, defecation, micturition, the sexual feeling, may all appear in an abnormal or unprovoked manner, and are to be classed as visceral paræsthesiæ. An important paræsthesia of this variety is met with in cases of hypochondriasis and melancholia; it is a sense of indescribable distress, with constriction, usually at the epigastrium and about the heart—the precordialangst of the Germans, or, as we would term it, præcordial anguish.

(h) Paræsthesiæ of the muscular sense occur. The subject has a feeling as if a part were lying in an unnatural position, or as if it were being pulled or twisted in various ways, and he is sometimes obliged to assure himself by the use of sight and by tactile examination that the sensation is illusory.

(i) Hallucinatory paræsthesiæ are those which are so well defined and strong as to need the aid of other senses and reasoning to convince the patient of their unreality. A peculiar example of this is what occurs after amputation of a limb: for days or weeks the lost member is felt with the utmost distinctness; the absent fingers or toes may be moved in imagination and their position described.

(j) Delusional paræsthesiæ are such in which the patient (usually

insane), no longer correcting his sensations by the use of other senses and by reasoning, firmly believes in their reality—*i. e.* externality. For example: in such patients visceral sensations give rise to the belief that there is a foreign body or an animal inside the patient, or that parts are misplaced or wrenched and beaten. Pains are thought to be due to blows received or to the bites of animals or projectiles thrown upon the patient. With perversions of muscular sense an insane patient may believe that he is flying or floating in the air.

In hypochondriasis many of the symptoms complained of are nothing but paræsthesiæ exaggerated by a morbid state of the mind, and sometimes created (projected) by expectant attention. The hallucinations of the insane are in great measure phenomena of this group, the projections, though special and common, never being so strong and definite as to acquire apparent objectivity.

The auræ of epilepsy are paræsthesiæ. For example: a sensation in the epigastrium preceding a fit indicates an irritation at the origin of the vagus nerve and its projection as a subjective sensation at the distribution of the nerve. An auditory or visual aura similarly represents a discharge or projection from the acoustic and visual cortical areas respectively.

In most cases of malingering, and in some cases of so-called railway spine, the symptoms so loudly complained of belong to the two classes of hyperæsthesiæ and paræsthesiæ; they are undemonstrable and non-measurable; only the patient himself can vouch for their reality. A diagnosis in such cases, without objective symptoms indicating well-known lesions, should be very reserved.

ANÆSTHESIA, or loss of sensibility, may exist in every degree, from one so slight as to be hardly demonstrable by delicate tests to the most absolute loss of all feeling. It manifests itself in various modes corresponding to the normal physiological varieties of sensibility; in most cases the loss of feeling involves all of these, but in others they are separately affected, and we observe the following types, pure or combined:

(a) Tactile Anæsthesia. The capacity to perceive superficial and gentle impressions upon the skin and mucous membrane, and the ability to locate and separate such impressions, may be lost, while other modes of sensibility remain normal.

(b) Analgesia is that condition in which painful impressions are not perceived, though common, caloric, or muscular sensibility may be normal or nearly so. Pricking, cutting, and bruising are unperceived. This, the most common variety, is usually met with in hysterical cases; it occurs at a certain stage of general artificial anæsthesia, in chronic alcoholism, extreme emotional states, and in hypnotism. Though a very striking symptom, it is not one of as serious meaning as loss of tactile or thermic sensibility. Often the patient is unaware of analgesia until tests reveal its existence.

(c) The sensibility of the skin to caloric is usually the last to disappear in the progress of an organic lesion, so that in certain cases (injury to nerves or spinal cord, myelitis, etc.) testing by ice or by a burning object is a sort of last resort. Before deciding in a given case that there is a complete break in the sensory tract, this test should be used as well as the application of the most intense induced electric current delivered upon the dry skin by a wire end.

In some cases of partial anæsthesia (*e. g.* in posterior spinal sclerosis) cold may be felt as heat and vice versâ, or pinching may be felt as burning, and be quite persistent.

(*d*) The so-called muscular sense may be greatly impaired or lost without ordinary anæsthesia. In such a case the subject is no longer directly and spontaneously aware of the exact position of his limbs, of passive motions done to them, and he executes voluntary movements with uncertainty. He is also unable to judge correctly of differences of weight in objects successively placed in his hand or hung from his foot. He needs the aid of sight to guide the affected limb and to judge of its position, etc. The awkwardness and uncertainty in voluntary movements by impairment of muscular sense must not be confounded, as is sometimes done, with ataxia, in which the attempted volitional movement is jerky and oscillatory, owing to the inharmonious action of antagonistic muscular groups.

(*e*) When a strong induced electrical current is passed through a muscle by means of wet electrodes applied to the skin, so as to cause a strong contraction, a special quasi-painful feeling, akin to that of cramp, is experienced in the contracting muscle, and is clearly distinguishable from the cutaneous sensation. This, the electro-muscular sensibility, may be lost independently of other modes of feeling and without loss of contractile power.

(*f*) Some observers claim that a special mode of sensibility exists in the skin by which varying degrees of pressure are estimated, independently of traction upon tendons and muscles (muscular sense), and that this may be separately impaired or lost.

(*g*) Visceral anæsthesia shows itself in the ordinary way by loss of that feeble degree of common sensibility which the internal organs possess, and also by impairment of their special functions, giving rise to anorexia, hydrodipsia, retention of feces and urine, loss of sexual feeling (without progeneral anæsthesia). Of course, these symptoms may be due to other conditions, and each case must be carefully studied. In the insane, visceral anæsthesia gives rise to delusions of emptiness, destruction of organs, and even, if coinciding with general cutaneous anæsthesia, to the notion that the body is dead or absent.

A singular phenomenon often witnessed is retardation in the transmission of an impression (usually a painful one). Thus, in testing the sensibility of the skin of the legs in tabetic patients, it is observed that instead of the normal, almost instantaneous, appreciation of the impression made by a needle-point, there is a lapse of two, five, ten, or even sixty seconds between the pricking and the signal of sensation by the patient. It should always be determined in such cases whether the retardation is peripheral and actual, or central and due to psychic conditions (dementia, absorption in a delusional state). Thus, in a case of profound melancholia we may observe extreme slowness and dulness of sensory impressions or complete anæsthesia; but the symptoms would have a very different significance, diagnostic and prognostic, from the same noted in a mentally clear patient.

An important result of impairment of sensibility is a reduction or loss of reflex movements originating from the area or organ which is anæsthetic. This is shown in anæsthesia of the distribution of the trigeminus

when the reflex protecting movements of the eyelids no longer take place, in atrophy of the optic nerve when the pupillary reflex actions are lost. In posterior spinal sclerosis we see several illustrations of this law: progressive degeneration of nerve-fibres in the posterior root-zones of the spinal cord, causing loss of patellar reflex, of vesical, rectal, and sexual reflexes, and in most cases of cilio-spinal reflexes and of muscular tonus. In these and analogous conditions one arc of the reflex mechanism is deranged, centripetal conduction is interfered with, and the reflex motor discharge can no longer be evoked.

That a similar pathological condition occurs in the cerebral mechanism, and may serve to explain many psychic symptoms, is very probable.

On the other hand, a destructive lesion may be so placed in the spinal cord or brain as to allow centripetal impressions to reach healthy spinal gray matter in the normal way, but preventing their passage frontad (upward) to be recognized by consciousness. In such a case we observe normal, or more commonly exaggerated, reflex action in parts which are insensible in the ordinary sense of the term. Indeed, in many cases the disconnected caudal portion of the spinal cord is in a state of vastly exaggerated reflex activity, as shown by the tetanoid and convulsive involuntary and reflex movements which take place in completely paralyzed and anæsthetic limbs (paraplegia from transverse myelitis). In general terms, it may be stated that when anæsthesia is due to lesions of peripheral nervous endings, of nerve-trunks, and of the posterior root system of the spinal cord, reflexes are diminished or lost.

It is often stated that anæsthesia causes ataxia of movement. This, from the results of experiments on animals and from clinical study, we believe to be a gross error. In animals and in man loss of sensibility gives rise to awkwardness or uncertainty in movement (increased if the eyes be closed) which is properly to be classed as a special variety of inco-ordination; but it is not from ataxia, in which irregular, jerky, oscillating motions occur when a volitional act is attempted, these movements resulting from want of harmony in the action of antagonistic muscles which in the normal educated state automatically act together to produce the desired result. Besides, we occasionally observe cases of typical spinal ataxia in which no impairment of sensibility can be observed.

THE TOPOGRAPHICAL DISTRIBUTION of alterations of sensibility requires careful determination in practice, as from it we obtain most valuable aid in diagnosis. The following are the principal types observed:

(a) Alterations of sensibility in one lateral (vertical) half of the body and head. We thus have hemihyperæsthesia, hemiparæsthesia, or hemianæsthesia, and the special senses on one side are frequently involved. This clearly hemi-distribution indicates that the lesion or functional disorder is in the cerebral hemisphere of the opposite side, more especially in the caudal segment of the internal capsule or in its areas of cortical distribution (occipital, temporal, and parietal lobes). The distribution of hemianæsthesia, etc. from organic disease in these parts is identical with that observed in some functional (hysterical) cases; we can make the diagnosis only by the help of other data.

If the sensory disorder does not affect the head, but is limited to one

lateral half of the body, it is, if due to organic disease, quite certainly of spinal origin.

(b) Two homonymous extremities or the two lateral halves of the body may exhibit opposite states of sensibility—anæsthesia on one side and hyperæsthesia on the other. This rare condition is witnessed in hysteria and in some forms of injury to the spine (lesion of one lateral half of the cord at a certain level). In the latter case paralysis is usually present on the hyperæsthetic side: the symptoms constituting, with some others, Brown-Séquard's spinal hemiplegia or hemiparaplegia.

(c) Alterations of sensibility in one caudal (horizontal) half of the body are said to have a paraplegic distribution, and are usually due to lesions of the spinal cord. The upper level of the symptom may be at any point between the neck and the toes; and the frontal (upper) level indicates, due regard being had to the origin and oblique distribution of the spinal nerves, the highest limit of disease in the nervous centres. Very often, in organic disease especially, this is also indicated by the presence of a cincture feeling (paræsthesia) at the frontal (upper) limit of the anæsthesia, etc.

(d) Disorders of sensibility may be limited to one extremity. This very rarely depends upon cerebral disease, and in such a case the anæsthesia, etc. is evenly distributed throughout the member, being most intense at its extremity, and being without sharp, distinct limits near the trunk. When due to diseases of the spinal cord, the cerebral (upper) limit of the symptom is usually clearly defined in accordance with the distribution of sensory nerves from the other (healthy) parts of the cord: a constriction band often marks the limit. Sometimes the peripheral anæsthesia, etc. is more or less in the territory of certain nerve-trunks. When we find the distribution of the sensory symptoms to coincide exactly in the areas supplied by the large nerves of the limb, without cincture feeling, it is certain that the lesions affect one or more of these nerve-trunks or the plexus above. In not a few cases the symptoms are due to hysterical or dyscrasic conditions, and the seat of the lesions (dynamic or molecular lesion) is uncertain. In judging of the distribution of anæsthesia, etc. in a limb due regard must be paid to variations in nerve-branching and to collateral nerve-supply.

(e) Alterations of sensibility occurring in well-defined areas of the hand, trunk, or extremities, corresponding to the known distribution of nerves, almost always indicates disease of the nerve itself, much more rarely disease in the spinal cord at the origin of the nerve. The reflexes are then diminished or lost. In judging such cases Van der Kolk's law of the distribution of the motor and sensory filaments of nerve-trunks should be remembered: it is, that of the two sets of fibres in a mixed nerve, the sensory fibres are distributed to parts which are moved by muscles which receive the motor fibres of the same nerve. Thus, in nerve lesions the chief sensory symptoms are always peripheral or distal from the chief motor symptoms.

(f) Disorders of sensibility sometimes appear in patches or irregular areas whose nervous connections are indefinite. Such patches of anæsthesia, hyperæsthesia, or paræsthesia sometimes indicate foci of disease in the spinal cord (and brain?); as, for example, the pains, etc. of posterior spinal sclerosis. These patches may also occur in consequence of inter-

ference with local circulation of peripheral parts; and we meet with them in such conditions as hysteria, neurasthenia, alcoholism, etc.

(g) Universal hyperæsthesia, paræsthesia, and anæsthesia may be observed. The last condition, in the insane, is very apt to give rise to delusions of non-identity and death of the body.

THE SENSORY DISTURBANCES OF THE SPECIAL SENSES are well worth separate consideration.

(a) Optic Apparatus.—Hyperæsthesia of the retina shows itself directly in photophobia, and indirectly (reflexly) by lachrymation and involuntary closure of the eyelids. Paræsthesiæ of the optic nerve and retina show themselves as flashes or projections of white or colored light in the visual field. These may be irregularly or generally distributed in the field, or appear as hemiopic (*vide infra*), or sector-like forms. Phenomena of this order may be experimentally produced by pressure on the eyeball or by the application of electricity over or near the eye. Photopsiæ of most varied sorts, as flashes, colored scotomata, or quasi forms may immediately precede epileptic seizures or attacks of migraine, constituting an optic aura. In some cases this assumes a definite picture form, when it partakes of the character of an hallucination. Anæsthesia of the optic nerve and retina varies infinitely in degree, from slight blurring or veiling of vision (amblyopia) to complete blindness (amaurosis). Another result is sluggishness or complete immobility of the iris under the action of light. As regards distribution, optic anæsthesia may affect the visual fields uniformly and generally, or it may assume definite geometric forms, or may appear in irregular patches (scotomata).

The definite geometric defects are classed under the general head of hemianopsia, by which term is meant that one horizontal or vertical half of the visual field is obscured. (1) Horizontal hemianopsia is not bounded by a very sharp or straight boundary-line, and is almost always due to intraocular disease (retinal lesions, embolism of one large branch of the retinal artery, injuries, etc.). (2) Vertical hemianopsia is usually marked by a sharply-defined vertical limit in the visual field, passing through the point of fixation, or a little to one side of it more usually, leaving central vision very acute. (a) Temporal hemianopsia, in which the temporal halves of the visual fields are dark, represents anæsthesia of the nasal halves of the retinæ, and is usually caused by a lesion of the chiasm of the optic nerve, so placed at its frontal or caudal edge as to injure the fasciculi cruciati. This variety is usually bilateral, but a lesion might be so situated as to affect only one fasciculus cruciatis. (β) Nasal hemianopsia, in which the inner (nasal) halves of the visual fields are dark, represents anæsthesia of the temporal halves of the retinæ, and is caused by a lesion injuring one fasciculus lateralis or both fasciculi. In the former case the nasal hemianopsia would be unilateral; in the second case, bilateral or symmetrical. (x) Lateral or homonymous hemianopsia is that condition in which physiologically similar halves of the visual field are darkened; for example, the temporal half-field of the left eye and the nasal half-field of the right. This represents anæsthesia of the nasal half of the left retina and of the temporal half of the right. The patient can only see, with one or both eyes, the right half of any object held directly in front of him. In such cases the lesion is always caudad of the chiasm, and may consist in interruption of the right optic tract,

of disease of the primary optic centres (*corpus geniculatum laterale* and *lobus opticus*) on the right side, of the caudo-lateral part of the right thalamus, of the caudal extension of the internal capsule or optic fasciculus within the right occipital lobe, of the right superior parietal lobule or *gyrus angularis* penetrating deep enough to interrupt the optic fasciculus; or, finally, the lesion may injure the visual centre itself—viz. the cortex of the right cuneus and fifth temporal *gyrus* (of Ecker). Hemianopsia of any type may be incomplete or only sector-like—*i. e.* involving only a quadrant or less of one visual field or of both fields. (Vide article on Localization).

Perception of color may be reduced, confused, or abolished in the retina, either a diffused general way, throughout the field of vision, or following the laws of hemiopic distribution. In cases of hysteria, achromatopsia is not rarely met with, affecting the eye corresponding to the side on which the skin is analgesic or where paralysis exists. Hysterical achromatopsia may be transferred from one eye to another by the application of metals, by hypnotic manipulations, etc.

Hemianopsic phenomena may be functional and transient, as witnessed just before attacks of migraine or sick headache.

Attempts recently made, from purely theoretical considerations, to locate centres in the occipital cortex for perception of light, form, and color separately, are wholly unjustified or at least premature.

Loss of reflex pupillary movements is a symptom of much importance. It occurs chiefly under these conditions: (1) with paralysis of the iris due to lesion of the third cerebral nerve; (2) with amaurosis or anæsthesia of the retina; (3) with posterior spinal sclerosis. The last condition is distinguished from the others by the fact that while the reflex iritic movements are lost, the quasi-voluntary movement of accommodation efforts is preserved. This condition is known as the Argyll-Robertson pupil.

Diplopia, or double vision, is due to paresis or paralysis of one or more of the ocular muscles, and as such is to be classed under motor symptoms.

Megalopsia (apparent enlargement of objects) and micropsia (apparent reduction in size of objects) are sometimes due to disorder of the accommodation apparatus within the eye, and to local diseases causing displacement of the rods and cones of the retina; but they are often, no doubt, fanciful (in neurasthenia and hysteria). The same remarks apply to monocular diplopia.

(b) Acoustic Apparatus.—We know less of the sensory disturbances in the organs of hearing. Hyperæsia shows itself by undue (painful) sensitiveness to sounds, and by the ability to perceive sounds which are inaudible to normal persons. In meningitis, hydrophobia, the hypnotic state, etc. this condition is observed. Paræsthesiæ are very common, appearing as subjective noises or musical tones (*tinntus aurium*) of the most varied kinds (roaring, hissing, blowing, tinkling, whistling, crashing, bell-sounds, etc.), which seem to the subject to be in his ear or in his head. In the present state of our knowledge it is impossible to positively distinguish *tinntus* due to local non-nervous ear disease from that which is strictly neural or cerebral in origin. Certainly, intense *tinntus* may coincide with complete anæsthesia of the acoustic nerve and a nor-

mal state of the middle ear. Theoretically, we may admit tinnitus (corresponding to photopsia in the optic apparatus) as due to an irritative lesion of various parts of the acoustic terminal nervous organ, the acoustic nerve, or the acoustic centre. An acoustic aura (subjective blowing, hissing, etc.) may immediately precede an epileptic attack. Subjective noises may be produced by excitation of the acoustic nerve and terminal organs by the galvanic currents; these galvanic acoustic reactions are regular in the normal condition, and are fully stated in works on electrotherapeutics. Anæsthesia of the acoustic system by peripheral, neural, or central (?) destructive lesions is frequent, and is distinguished from other forms of deafness chiefly by the fact that a sound transmitted through the bones of the cranium (as by a vibrating tuning-fork held against the upper teeth or above the ear) is not heard on one or both sides. Although in a few rare cases the attempt has been made to define nervous deafness for certain sets of notes or as limitations at either end of the musical scale, yet we are not prepared to recognize in neurological practice a condition of partial acoustic anæsthesia corresponding to hemianopsia or achromatopsia. We believe that this progress will be made, however, thus enabling us to locate disturbances in parts of the organ of Corti and in the cortical centre for hearing.

(c) *Olfactory Apparatus*.—Hyperæsthesia of this sense is at present considered more a personal peculiarity than as a symptom of disease. Paræsthesiæ show themselves as subjective odors of various sorts, and when transient may be an olfactory aura preceding epileptic attacks. In conditions of organic disease subjective odors may coincide with complete loss of smell. Anæsthesia of the olfactory nervous apparatus may be due to (1) strictly local disease in the nose, catarrh, etc.; (2) to anæsthesia of the trigeminal nerve and consequent local lesions; (3) to a truly nervous lesion affecting the olfactory nerves, the olfactory bulbs, the olfactory tracts, or, lastly, the cortical centre for smell (at present unknown in man). The two last morbid conditions are usually unilateral, and coexist with subjective odors.

(d) *Gustatory Apparatus*.—In this sense hyperæsthesia is clinically unknown, though as a result of education extreme delicacy of taste, a relative hyperæsthesia, may be produced. Paræsthesiæ are rare. In two cases in which we have observed the symptom (one of neurasthenia, the other of hypochondriacal melancholia) it consisted in a constant and most distressing sweet taste. The application of the galvanic current at the base of the brain, under the jaw, on the cheeks, and within the mouth produces subjective tastes of an acid or metallic nature. Anæsthesia of the gustatory nerve occurs after section of the lingual branch of the trigeminal—an operation sometimes done for lingual neuralgia, in which case the frontal two-thirds of the tongue on one side loses its property of perceiving taste. As the result of central disease next to nothing is known of this symptom. It is probable that sweet and acid tastes are perceived in the mouth and forward part of the tongue; bitter tastes on its caudal (posterior) third and in the throat (glosso-pharyngeal nerve). In the insane, paræsthesiæ and anæsthesia give rise to a great variety of delusions about the state of the parts, the nature of their food, poison in the food, etc.

As a part of typical complete hemianæsthesia the special senses are

involved. When of hysterical origin the whole retina of one eye is generally devoid of sensibility, or it does not perceive colors. When the hemianæsthesia is due to a lesion of the caudal part of the internal capsule (organic anæsthesia), we should expect to find lateral hemianopsia, with dark half-fields on the same side as the cutaneous anæsthesia. We would not be understood as claiming that this point of distinction is as yet positively determined, but would advance it suggestively, subject to the result of observations on new cases.

III. Motory Symptoms.

PARALYSIS, or AKINESIS, is a condition in which loss of voluntary or involuntary muscular movement occurs through defective innervation. Such a strict definition is desirable, as excluding cases in which motion is abolished by local or general morbid states not essentially nervous, as in acute articular rheumatism, ruptures of muscles or tendons, fractures, extreme asthenia, etc.

Paresis is a term often employed to designate a paralysis partial in degree; it does not mean an essential muscular paralysis.

Paralysis varies infinitely in extent and distribution, yet certain types are recognized as having diagnostic value, and their exact determination is of great importance in practice.

(a) Hemiplegia, or paralysis of many muscular groups in one lateral half of the body.

(a) Common Hemiplegia.—In this, the most frequent form, we find loss of voluntary motion in many muscles of one side of the face and body. This condition may or may not be preceded by apoplectic or epileptic symptoms: it may occur gradually or suddenly. Although it is customary to say that in hemiplegia a patient is paralyzed on one side, this is not strictly correct, as careful observation shows that (1) in the face only the lower facial muscles are distinctly affected; the tongue itself is rarely paralyzed, but its projecting muscular apparatus is, so that when protruded it deviates as a whole toward the paralyzed side; the eye-muscles and masticatory muscles are unaffected; (2) in the extremities the loss of power is greatest in the hand and foot, less so in the arm and thigh, very slight in the muscular groups of the shoulders and hips; (3) the muscles of the neck and trunk, the respiratory muscles, and in general the muscles of the vegetative life are practically unaffected. These facts may be summarized by the statement that in common hemiplegia the greatest paralysis is shown in those muscular groups whose action is most independent on either side of the body; or, in other words, in those whose functions are most highly differentiated and whose innervation is most cortical (from the motor centres in the cerebral cortex). Those muscular groups, on the other hand, whose action is usually or necessarily simultaneously bilateral or associated across the median line—or, in other words, whose innervation is largely spinal or subcortical—are least paralyzed; while the purely automatic or reflex muscular apparatuses, those having a strictly spinal or sympathetic innervation, are not at all affected.

Common hemiplegia is rarely accompanied by hemianæsthesia.

It must not be forgotten that double hemiplegia may occur, in which case the symptoms are simply duplicated.

As regards the seat of the lesion in common hemiplegia, it may here be said, in general terms, that it is in the cerebral hemisphere opposite to the paralysis (with excessively rare exceptions which are susceptible of explanation), in its motor cortex, in the subjacent associated white fasciculi, or in the knee and caudal part of the internal capsule; the lesion may directly injure those parts or act upon them by compression.

(β) Crossed Hemiplegia (*hémiplégie alterne*).—In this form there is paralysis of many muscular groups on one side of the body, while the facial nerve or some other cranial nerve (or several cranial nerves together) show loss of innervation on the other side of the median line. Theoretically, therefore, there may be as many varieties of crossed hemiplegia as there are cranial nerves, but, practically, we meet only with a few forms, of which the following are the most common: (1) motor oculi (N. iii.) on one side, and body and face on the other; (2) facial nerve (N. vii.) on one side, and body on the other; (3) trigemimus nerve (N. v.) on one side (anæsthesia of face, paralysis of masticatory muscles), and body on the other; (4) abducens (N. vi.), facial (N. vii.), and acoustic (N. viii.) together on one side, and the body on the other. (5) With symptoms of No. i. we may have lateral hemianopia, dark half-fields on the same side as paralyzed extremities.

In crossed hemiplegias anæsthesia is more common; there is a strong tendency to bilateral extension of the paralysis, and neuro-retinitis is seldom absent before the close of life.

As regards the location of the lesion in crossed hemiplegias, it may be stated, in a general way, that it is in the base of the brain on one side of the median line, so placed as to directly injure one or more cranial nerves at their origin, and to compress or destroy the cerebral motor tract (pyramidal tract) above its decussation-point, and in some cases also the sensory tract in the crura, pons, and oblongata.¹

(b) Spinal Hemiplegia.—In this type the face and head are normal, excepting in some cases the iris; the extremities and trunk are more or less paralyzed on one side, the loss of power being more evenly distributed (*i. e.* less distal) than in hemiplegia of cerebral origin. Often there is also anæsthesia, and this is always on the other side of the median line, involving more or less of the whole side. The coincidence of these symptoms below the head indicates positively that the lesion is in the spinal cord, involving one of its lateral halves. Where there is no anæsthesia, care must be taken not to confound the condition with that in which a cerebral lesion causes paralysis of one arm and leg (combined brachial and crural monoplegia).

(c) Paraplegia.—The loss of voluntary power involves one transverse half of the body, usually the caudal. When only the lower extremities are affected, the condition is designated simply a paraplegia; when all the parts below the head are paralyzed, the term cervical paraplegia is employed. Frequently, the bladder and rectum are paralyzed, and in some cases the thoracic muscles also, leaving inspiration to be performed by the diaphragm alone. Often there is coextensive anæsthesia.

¹ For a statement of the exact seat of the lesion causing various forms of crossed hemiplegia, vide article on the LOCALIZATIONS OF LESIONS IN THE NERVOUS SYSTEM.

Hemiparaplegia is a rare variety in which one lower extremity is paralyzed while the other is anæsthetic.

The location of the lesion in paraplegias is in the spinal cord at various levels and in various portions of the gray and white columns. Theoretically, we may now again admit the old proposition that a paraplegia may be of cerebral origin: in such a case the loss of power should follow the laws of distal prevalence (*vide* (a)); there should be no anæsthesia or vesical paralysis, and the lesion ought to be one involving the paracentral lobules of both hemispheres (meso-vertex at fissure of Rolando).

(d) Monoplegia, or paralysis of one extremity or of one side of the face, is not rarely observed. It may be caused by central lesions in the brain or spinal cord, or by an affection of the nerve-trunks of the part. Cerebral monoplegias are of great importance in diagnosis, and may be distinguished from others by—(1) loss of power is greatest in the distal part of the affected member; (2) the precedence or coincidence of spasm (usually clonic or epileptiform) in the limb; (3) the absence of marked anæsthesia; (4) the preservation of muscular nutrition.

(e) Localized Paralysis.—The extreme types of this form of paralysis are paralysis of one external rectus and of one superior oblique. These muscles are each supplied by one whole nerve, and may therefore exhibit isolated paralysis. In the rest of the body, however, localized paralysis shows itself in groups of muscles as innervated by nerve-trunks or by certain so-called centres in the spinal cord. As examples of the former variety may be cited common facial paralysis (Bell's palsy) and paralysis of the extensor muscles of the hand by injury to the musculo-spinal (radial) nerve, of the foot and leg from lesions of the sciatic nerve. As examples of the second variety we have the irregular paralysis of anterior poliomyelitis (infantile spinal paralysis). In localized paralyses due to lesion of the nerve-trunks anæsthesia is usually present, whereas it is not common in the second variety. The determination of the seat of lesion in neural localized paralysis is much facilitated by bearing in mind Van der Kolk's law of the distribution of the motor and sensory fibres of a nerve-trunk.

Pseudo-paralysis—*i. e.* conditions in which voluntary motion is lost without defect in innervation, as from muscular disease, injuries, inflammations, etc.—is usually localized or irregularly distributed.

(f) The various internal organs, the viscera, supplied with striped or unstriped muscular fibres, may be paralyzed.

(g) The muscular coat of the vascular system beyond the heart may be paralyzed in extensive or limited areas—the so-called vaso-motor paralysis. This may assume hemiplegic or monoplegic or localized forms.

SPASM, or HYPERKINESIS, consists in abnormal and often violent involuntary muscular contractions, with or without loss of consciousness.

1. A purely mechanical classification of spasms into tonic and clonic forms is generally admitted as serviceable for clinical description, though we have as yet no positive knowledge of their relations to pathological conditions.

(a) Tonic or tetanic spasm is one in which the muscular contraction is continuous or constant for a measurable length of time. Thus, in some cases of petit mal there is a momentary stiffness or rigidity of the entire

voluntary muscular apparatus (respiratory muscles included): the patient sits or stands with staring eyes as if petrified. In tetanus and local tetanoid seizures the muscles of large regions or of a part of a limb may remain contracted for many minutes; in the disease called tetany this condition may endure days and weeks—in hysteria and in some paralyses dependent upon organic disease for years or permanently. Prolonged tonic spasms occurring in chronic diseases are designated as contractures, and the affected parts are said to be tetanoid or spastic. A tonic spasm of long duration may show itself in involuntary muscles, as in the arteries, causing vaso-motor spasm and ischæmia; in the ciliary muscle, causing spasm of accommodation; in the urethra, œsophagus, etc.

A tonic muscular contraction accompanied by intramuscular pain is termed cramp.

Under this general head may also be classed the emotional or dramatic expressive spasms of hysteria and hystero-epilepsy—a condition in which the emotions or ideas occurring in the patient's mind are involuntarily translated externally into attitudes or gestures: *e. g.* anger, fear, disgust, amorous and religious feelings, etc.

(b) Clonic spasms are those which consist in rapidly intermittent muscular contractions, local or general. These may be rhythmical in time or form, as in paralysis agitans, or wholly irregular, as in chorea. Jerking is a quasi-popular designation of clonic spasms.

Tremor, or trembling, observed in persons during repose in any attitude, consists in small, wholly involuntary muscular contractions of sufficient extent to communicate to the parts a visible to-and-fro movement which is very often rhythmical. In order to distinguish this from any form of inco-ordination it is necessary that the observed movement should occur independently of all volitional effort. Thus in the senile state, in chronic alcoholism, in paralysis agitans, and in dementia paralytica we observe trembling of the facial and lingual muscles, of the extremities, and even of the whole body in some cases. These are usually conditions of permanent or chronic tremor, but the symptom is sometimes observed as a transient phenomenon, as after violent muscular effort, after excesses of various sorts, under the influence of emotions, etc. Occasionally, persons are met with who have trembled from childhood or early years without actual disease of the nervous system. It is clinically useful to divide tremor into varieties, as rhythmical and irregular, fine and coarse, constant and occasional. These terms define themselves sufficiently, so that no further statement is necessary, but we would repeat that it is of much advantage in diagnosis to determine accurately the characteristics of tremor.

2. A much more useful classification of spasms, and to a certain extent a physiological one, is into types according to their distribution in the body, following exactly the classification of paralyses. There are few topics of more utility for the physician to study, in our opinion, than that of monoplegias and monospasms, of hemiplegias and hemispasms in their genesis, mutual relations, and diagnostic significance.

(a) Hemispasm of cerebral origin, tonic or clonic (or both forms associated), may affect the face and limbs on one side of the body, with or without paralysis. As in hemiplegia, the morbid phenomena are greatest in the most distal muscular groups or in those whose innervation is most

cortical. Very often hemispasm precedes, immediately or remotely, hemiplegia in the same parts. In other cases the relation is inverse, as when, after a severe hemiplegia, we find the paralyzed muscles in a state of nearly constant tonic contraction (secondary contracture), or when hemi-epilepsy follows a cerebral lesion. In the former case the spasm, clonic or tonic, is designated as pre-paralytic; in the second case, as post-paralytic. These terms are useful, because they are associated with laws of diagnosis and prognosis.

(b) Conjugate deviation of the eyeballs and head is an important symptom of gross cerebral lesions, and may be considered here, although it is probably due to paralysis. Still, the deviation itself always strikes the observer as a spasmodic effect. The symptom consists in a steady turning of the eyes, face, and head toward one or the other side, and may be best described by likening it to the normal act of looking at an object which is on one side or a little back of us. In one form—that due to an irritative lesion of the motor cortex of one hemisphere—the conjugate deviation forms a part of the hemiplegic epileptiform convulsions (mixed tonic and clonic) which are produced: the deviation is away from the lesion. In a second form, where severe hemiplegia is produced by an acute lesion of the motor area and the subjacent fasciculi of one hemisphere, whether the patient be comatose or semi-conscious, the deviation, of paralytic origin, is away from the paralyzed side of the body and toward the injured hemisphere: the patient is said to be looking at his lesion. In a third form, when the lesion is in one side of the base of the brain (more particularly of the pons), the deviation, again paralytic, is away from the lesion, as a rule. In some cases conjugate deviation exists only as a tendency to look to either side. It is always a valuable symptom in severe cerebral affections, more especially the apoplectic state.

(c) Paraplegic spasm is also shown in tonic and clonic forms. Partial tonic spasm of this distribution, with paresis of the legs, causes the gait or attitude known as tetanoid or spastic. The four extremities may be in this state of mixed paresis and contraction, as observed in some very young children whose cerebral motor area is probably undeveloped or ill-developed, or which has been damaged shortly after birth by meningeal hemorrhage.

(d) Monospasm, spasm affecting one side of the face or one extremity, may be of cerebral, spinal, or neural origin. Very often monospasm of clonic form serves to indicate with wonderful precision beginning disease (irritation stage) in limited parts of the cerebrum (in cortical centres and in the connected fasciculi for the face and limbs). Cerebral monospasms are sometimes combined so as to almost constitute hemispasm—*i. e.* brachio-facial or brachio-crural monospasm. Monospasm may precede or succeed monoplegia.

(e) Universal spasms, tonic, clonic, or mixed, occur in numerous diseased states—in hysteria, epilepsy, chorea, tetanus, toxic conditions, etc. A universal tonic spasm may last long enough (tetanus, epilepsy) to kill by apnoea.

(f) Localized spasms, not monoplegic, are observed. For example, the orbicularis palpebrarum may be the seat of clonic spasm, or the masseters of tonic spasm for long periods of time; the oesophagus or urethra may be temporarily closed by constriction; chorea may affect a small muscular

group. A rhythmic spasm limited to a single muscle is termed *myoclonus*; the use of this term should not lead one to forget the nervous origin of the spasm. A localized tonic arterial spasm may be so severe and prolonged as to produce great ischæmia, even gangrene of the affected part.

(g) Fibrillary contractions, non-rhythmic contractions of fasciculi in muscles, spontaneous or provoked by direct mechanical excitation, may be considered as hyperkinesis. Subjectively, fibrillary contractions are felt as a quivering or as if a worm moved under the skin; objectively, they appear not unlike the rising and falling of a cord under the cutaneous covering. They unquestionably occur frequently in muscles which are undergoing degenerative or atrophic changes (progressive muscular atrophy), but they are also met with in cases of lead paralysis, neurasthenia, ect.

INCO-ORDINATION, or *DYSKINESIS*, is the condition in which volitional movements are not performed with normal precision and steadiness. Several varieties are recognized.

(a) Ataxic tremor is distinguished from common or spasmodic tremor by the fact that it is developed during the performance of a volitional act in parts which are quiet when not used. Thus, tremor appears in speaking, putting out the fingers, using the hands, etc. in the muscles actively employed, and occasionally also in others at the same time. This form of tremor is well seen in *dementia paralytica*, where in certain cases the patient's muscles are still until we induce him to make voluntary movements or provoke expression movements. In cases of disseminated sclerosis the same phenomenon is a characteristic symptom, a coarse tremulous ataxia or oscillatory trembling appearing whenever volitional acts are attempted. In looking, there appears nystagmus, a rhythmic ataxic tremor of some of the ocular muscles; in speaking, an irregular, jerky, slow, or syllabic speech is heard; and when the hand is carried to a given object or pointed the extremity exhibits oscillatory trembling. Common and ataxic tremors may coincide, as in some cases of *dementia paralytica* and in alcoholism.

(b) Ataxia is a symptom of the utmost importance, and its strict definition should be maintained. It is that form of inco-ordination in which there is want of harmony in the action of the various muscular groups employed in the voluntary performance of a given act. The simplest movement of an extremity (and more complicated ones *a fortiori*) is made up of simultaneous contractions of flexor and extensor muscles, often also of adductors and abductors in due proportion, so as to produce a steady position and movement of the parts. This is not accomplished by the will acting directly on the different muscles themselves, but through the medium of a co-ordinating mechanism which is strictly spinal (including the intracranial expansion of the cord as far forward as the third ventricle), and which is educated or trained from the first days of life. We will the action and set the co-ordinating mechanism going, so that the movement is in a certain sense indirectly accomplished. Yet volition does interfere directly to a certain extent by estimating through the muscular sense, and by exerting the proper amount of force required, and by guiding the movement in a general way. The most striking peculiarity about ataxic movements is the defect in the harmonious action of the various (antag-

onistic) muscles employed, resulting in jerky, oscillatory, but non-rhythmic movements, constantly made worse by greater tension of the will. In simple tremor volition may for a few moments stop the movements (as best shown in paralysis agitans), while in ataxia the more the patient tries to achieve the act, the greater becomes the disorder. The anatomical fault is mostly in the spinal co-ordinating mechanism; the long-established motor and sensori-motor associations are interrupted or confused, and in some cases besides the muscular sense is impaired.¹ The idea that ataxia results from faulty centripetal impressions due to various degrees of anæsthesia is certainly erroneous and misleading. In the first place, there are cases recorded in which typical ataxia of the extremities occurred without the slightest impairment of sensibility; and, secondly, neither in animals (section of posterior roots of spinal nerves) nor in man does ataxia appear as a result of anæsthesia. In this condition there is inco-ordination, to be sure, but not ataxia in the strict meaning of the term. Ataxia is nearly always a symptom of organic disease of the spinal cord, more especially posterior spinal sclerosis and diphtheritic myelitis. It may also occur from disease of the oblongata, pons, and crura cerebri. In certain cases of lesion in caudo-lateral part of the thalamus involving the caudal part of the internal capsule (irritation or partial destruction), we observe various forms of irregular movements which have been designated by Weir Mitchell as post-paralytic chorea. We long ago became satisfied that this term included quite a number of forms of inco-ordination, some cases showing choreiform and trembling movements, others ataxic tremor, true ataxia, and athetoid movements (also the true athetosis of Hammond?). It seems probable that diseases of the cerebellum, by exerting pressure on or by irritating subjacent parts, may sometimes cause pure ataxia of the extremities on the side opposite the lesion. That a strictly localized cortical lesion can give rise to ataxia we are not now prepared to admit.

(c) Uncertainty in voluntary movements is sufficiently defined by the term employed and by the absence of ataxia. This is well illustrated in those rare cases in which the muscular sense is impaired or lost: in such a case volitional movements, such as placing the fore finger on an object or fastening a button, are fairly well done with the aid of sight, but without it the hand and fingers grope almost or quite hopelessly about the object. It is important to note that persistent trying to do the act does not aggravate the disorder, but that, on the other hand, success is often achieved after feeling about. In certain cases of blindness irregular movements of the eyeball are observed, due to semi-voluntary efforts to look or to direct the eyeballs in the direction of a person or object. In states of cutaneous anæsthesia when the eyes are closed the same disorder appears in muscular movements. Claude Bernard many years ago showed that section of the posterior roots of spinal nerves in an animal was followed, not by ataxia, but by vague inco-ordination and staggering. In human cases we find that where the sensibility of one hand is lost or greatly impaired, without paralysis, there is extreme awkwardness and uncertainty in delicate muscular movements, but no ataxia. The staggering exhibited by patients having plantar anæsthesia is largely of this type: they stand fairly well while their eyes are open, but oscillate or

¹ Ataxia is greatly aggravated by closing the eyes.

fall when they are closed. This variety of inco-ordination may result from toxic conditions (alcohol), peripheral, neural, or central nervous disease. A few cases are on record which would seem to show that there is a centre for muscular sense in the cortex of the brain, in a part intermediate between the caudal sensory area and the central motor one—viz. in the inferior parietal lobule, supramarginal gyrus (and angular gyrus?). It has also been shown (by Spitzka and others) that there is a conduction tract for muscular sense, dorsad of the pyramidal tract in the pons and oblongata (in the stratum intermedium and interolivary tract), lesions of which produce inco-ordination (ataxia?) without marked paralysis or anæsthesia.

(d) Titubation, or staggering, is the inability to stand erect or walk straight because of impaired equilibrium. There is neither tremor nor ataxia present, and paralysis and anæsthesia are not necessary factors. It is distinguished from vertigo and dizziness by absence of subjective sensations of movement. Staggering may show itself in a general way or in the shape of latero-, retro-, or propulsion (disease of the internal ear, paralysis agitans). A well-defined variety of staggering is the wrongly-termed cerebellar ataxia. In this the patient, having disease of the cerebellum involving its vermis superior, stands with feet widely separated to increase his base of support; the body is bent somewhat forward, and the arms and hands are used as balancing-rods to maintain a sort of equipoise. In walking, this attitude is exaggerated, and if the feet be bare it will be seen that the toes are unconsciously clutching the floor for support; there is no outward jerk of the leg or stamp of the heel as in the ataxic gait, and closing the eyes does not aggravate the attitude or walk. Besides, if the extremities be separately tested, it is found that with closed eyes the patient can perfectly well place his fore-finger on his nose or one heel on the opposite patella (lying down). The proper term for the disorder is cerebellar titubation. Yet it must be remembered that titubation also occurs from disease of the oblongata and pons, from lesions of the base of the brain in general, and from alcoholic, etc. intoxication. In many cases titubation occurs in connection with vertigo or dizziness.

(e) Inco-ordination more or less of the ataxic form often affects the muscles of articulation, phonation, and deglutition, giving to the symptoms dysarthria, dysphonia, and dysphagia. Dysarthria and dysphagia are probably often caused by lesions of the insula and subjacent white substance, as well as by those affecting the oblongata. There are two recent autopsies which would indicate that there may be a cerebral cortical centre for phonation laryngeal movements: in the ventral extremity of the right third frontal gyrus—a part homologous to the speech centre on the left side of the brain. In some cases, however, dysphonia and aphonia indicate a lesion of the laryngeal nerves or of the oblongata (nucleus of NN. x. and xi.).

(f) Doubtless the internal muscular organs and the blood-vessels are frequently the seat of inco-ordinate or quasi-ataxic movements, but our present knowledge of these conditions amounts to very little.

It may be permissible to consider vertigo under the general head of inco-ordination, because it usually finds a motor expression, either actual or subjective. Subjective vertigo consists in a sense of whirling or horizontal movement which is clearly referred to the brain by the patient. The

sensation is variously expressed: in some the head seems to whirl around; in others external objects seem to whirl about the patient horizontally or vertically; in others still there is a sensation of falling in a given direction or of dropping into a hole. Dizziness is a minor degree of subjective motion conjoined with more or less confusion and other paræsthesiæ in the head. Static vertigo is that form in which there is actual loss of equilibrium, or falling. It is observed more especially in diseases of the internal auditory apparatus, and it may be produced artificially by galvanization of the brain. If the electrodes are placed exactly on the median line, and the current passed fronto-caudad through the brain, no loss of equilibrium or vertigo is produced. If, however, the current is passed transversely through the brain, there is produced at the moment of the closure and opening of the circuit a distinct tendency to fall or an actual fall to one side: in closing the current the fall is always away from the negative pole or cathode. The greatest amount of disturbance is produced when the electrodes are placed on the mastoid processes or near them. Whether the disturbance of equilibrium is caused by a change in electrotonus in the hemispheres, or by a change in the vascular supply of the hemispheres (in one anæmia, in the other relative hyperæmia), is uncertain. A third explanation is equally plausible—viz. that the vertigo is caused by unequal excitation of the internal acoustic organs and the two halves of the cerebellum. This view would be supported by the fact that in animals and man a lesion of the acoustic nerve and of the processus ad pontem on one side produces strong rotary movements about the long axis of the body.

ABNORMAL REFLEX MOVEMENTS.—Some reference has already been made to absence or exaggeration of reflexes in the preceding paragraphs, but the importance of these symptoms demands that they should be separately considered.

A reflex action, in its simplest conception, is a movement (muscular, vascular, or psycho-motor) or a secretion which is the result of the transformation of a centripetal impression into a centrifugal impulse. The apparatus required for the accomplishment of the reflex action consists essentially of a sensitive surface of skin or mucous membrane, of tendinous or other deep structure, to receive the impression; a sensory afferent nerve to convey it; a nervous centre of the simplest structure (one or two ganglion cells) to receive and transform it; a motor or efferent nerve to transmit the resulting impulse to a common muscle, to the vascular wall of a vessel or viscus, or to a gland. These various terminal organs execute their normal functions in response to the centrifugal impulse, and thus give external or tangible evidence that the reflex action or reflex is completed. This mechanism, the reflex arc, is illustrated by the diagram (Fig. 1), which will also serve for the explanation of many of the morbid reflex states.

In the healthy animal body many important functions are performed under the law of reflex action; for example, many organic or secretory functions, the movements of hollow viscera, vascular movements, muscular tonus, defensive and expressive muscular movements. In the process of education many acts which at first must be learned by oft-repeated efforts, such as walking, playing upon musical instruments, etc., later become habitual and automatic, and are then largely executed by reflex

action unconsciously, co-ordinated by the spinal (?) apparatus. Much of our intellectual activity is governed by the same law operating between the psycho-sensory and the psycho-motor apparatus.

Reflex actions are only to a moderate extent under the control of volition—indeed, most of them are subconscious—but a strong restraining action is unconsciously exerted by the cerebrum (vide Fig. 1) upon the spinal reflex centres. This is the so-called inhibitory cerebral influence. The existence of such an influence is shown by experiments upon animals,

Diagram illustrating the Arc for Reflex Action. The centripetal and centrifugal paths, the receptive and terminal organs of the arc, are shown connected with a spinal centre, which is a portion of central gray matter containing ganglion cells. The inhibitory cerebral influence is constantly exerted in health to moderate reflexes.

and by human cases in which, the cerebral activity being reduced or abolished, we observe a great increase in the frequency and extent of reflex movements, particularly in the common muscular apparatus.

Clinically, we distinguish cutaneous or superficial, tendinous or deep reflexes, according to the seat of the original excitation or testing-point. Cerebral or psychic reflexes are, however, also to be borne in mind. These reflexes may be abolished or increased.

(a) Diminution and abolition of reflex action are frequent symptoms of disease of the nervous system. The fault or break may be anywhere in the reflex arc, so that each case must be analyzed by itself. Let us consider the phenomena as exhibited by two widely distant and different apparatuses.

First, in the eye. In case of atrophy of the optic nerve the pupillary reflex is lost, the reflex action failing because the receptive surface and efferent nerve are injured. In certain cases of spinal disease (posterior spinal sclerosis) the same pupillary immobility is observed (the Argyll-

Robertson pupil); and in this case the lesion either affects indirect efferent spinal fibres destined for the iris, or it is situated in the centre for the reflex action—viz. the gray matter of the lobus opticus. There may be loss of pupillary reflex due to injury of the direct efferent fibres of the arc (paralysis of the motor oculi, N. iii.). Lastly, the iris itself may be so diseased as to be incapable of contracting, though it receive the reflex impulse properly; the lesion is then in the terminal organ of the arc.

Second, the patellar tendon reflex. In a healthy individual, sitting at ease with one leg thrown over the other (knee over knee), upon tapping the ligamentum patellæ of the overhanging or free leg a contraction of the quadriceps muscle occurs, causing a visible forward movement of the leg and foot. This is the well-known patellar reflex or knee-jerk. The arc in this case consists of the ligamentum patellæ with its included sensory fibres as receptive organs, sensory (afferent) fibres of the crural nerve, a segment of the lumbar gray matter of the cord as centre, motor (efferent) fibres of the crural nerve, supplying the quadriceps extensor femoris, which is the terminal organ. Theoretically (vide Fig. 1), we can conceive of numerous abnormal conditions of parts of this arc which would lead to abolition of the patellar reflex, but in practice the following are the principal lesions to be thought of: Disease (sclerosis) of the posterior root-zones of the lumbar enlargement of the cord, as exhibited in the pre-ataxic stage of tabes; disease of the posterior roots themselves through meningitis or meningo-myelitis, as in diphtheritic ataxia; lesion of the nervous centre, as is frequently observed in cases of infantile poliomyelitis; a lesion of the crural nerve, involving its efferent or afferent fibres, or both sets of fibres, would produce the same result, as would also, lastly, a severe myositis or cancerous infiltration of the quadriceps muscle.

It is therefore evident that there is, or can be, nothing pathognomonic in the loss of a given reflex: it simply indicates a break in the reflex arc, the seat and nature of which remain to be determined in each case. The topographical study of reflexes in disease is of very great importance, more especially as a help to the correct location and extent of neural and spinal diseases. To assist this study, and for use more especially in connection with the ensuing sections on localization, Gowers's excellent diagram and table are reproduced on p. 53.

(b) Exaggeration of reflex actions. This is due, theoretically, to any condition which increases the excitability of the reflex arc, but practically and usually the cause of the increase is more or less complete removal of the inhibitory supraspinal or cerebral influence. The reflex arc itself remains structurally sound, but its function is abnormally active. Thus, we meet with the most exquisite exhibition of exaggerated reflexes in the paralyzed part after a transverse lesion of the dorsal part of the cord. The lesion cuts off all communication between the lumbar enlargement and the brain; no sensations pass to consciousness, and no volitional influence can be exerted upon the legs; yet the legs are abnormally active, the least touch on or pricking of the skin, tapping a tendon, handling a joint, the pressure of feces in the rectum, etc., produce more or less violent spasmodic movements of mixed clonic and tonic forms (spinal epilepsy). Increased knee-jerk, foot-clonus, and epileptoid trepidation are also present. Other proofs that removal of the inhibitory cerebral influences is the chief cause of increase of spinal reflexes are given by the

FIG. 2.

Diagram and Table showing the Approximate Relation to the Spinal Nerves of the Various Sensory and Reflex Functions of the Spinal Cord (after Gowers).

history of various cerebral diseases. Thus, in hemiplegia with secondary contracture the cutaneous and tendinous reflexes on the paralyzed side are much exaggerated; in dementia paralytica, as a rule, the patellar reflex is increased on both sides; and in cerebral neurasthenia all reflexes are often extremely great.

A variety of increased tendon reflex is known as clonus—a series of rhythmic clonic muscular contractions set up by stretching the body and tendon of a muscle. This is best studied at the ankle. By holding the patient's leg nearly extended upon our left hand, and rather suddenly forcing back the foot (dorsal flexion) by pressing under the ball of the foot with our right hand, a series of oscillations or to-and-fro movements of the ankle-joint are produced for a few moments (ankle- or foot-clonus). Sometimes the same rhythmic clonic contractions may be produced in the quadriceps by quickly pulling down the patella with the leg semi-extended.

In some instances, together with great increase of tendon reflex, we observe a transfer of the centrifugal impulse to other nerves of the same extremity, or across the spinal cord to nerves and muscles of the homologous limb.

Another interesting manifestation of morbid reflex movements is the defensive tonic spasm of muscles about a diseased joint (of the hip-muscles in coxitis, of vertebral muscles in Potts' disease). This constitutes a valuable symptom for the differential diagnosis between articular and neural diseases in certain cases.

Clinically, increase of reflex action is not as valuable an indication as its absence, many healthy persons having high reflexes. Still, when studied comparatively as to topography (comparing the two sides of the body) and as to variations at different times in a given case, the symptom is of considerable assistance.

IV. Trophic Symptoms.

Our present knowledge of this great group of symptoms of nervous disease is in a somewhat chaotic state; and although we possess a large accumulation of facts of this category, their classification is incomplete and their explanation is for the most part theoretical and unsatisfactory. The following subdivisions may be made to include all the phenomena, and is sufficient for clinical purposes:

1. **DEGENERATIVE ATROPHY**, as distinguished from the simple atrophy of insufficient nutrition, of disuse of the parts, and of retarded growth, includes all those trophic symptoms in which, under the influence of nervous disease, the solid tissues exhibit histological and chemical alterations as well as reduction of volume. The principal factor of this group is—

(a) Muscular atrophy due to lesions of some part of the nervous apparatus (thus excluding directly traumatic or inflammatory atrophy), as seen in the course of progressive muscular atrophy, of various forms of poliomyelitis, of lead paralysis, of neuritis, and injuries of nerves. These muscular atrophies are characterized by reduction in the size of the affected muscles, by altered electrical reactions, and by histological

changes. Reduction in size may affect one muscle or a muscular group shortly after paralysis (as in poliomyelitis, lead paralysis, affections of nerve-trunks), or without evident paralysis it may involve only small fasciculi of a muscle at a time (as in progressive muscular atrophy); so that we speak of diffused and fascicular atrophy, of secondary (post-paralytic) and primary atrophy. In some cases the wasting proceeds to such a degree that apparently no muscular tissue remains, and the skin seems to rest directly on the bones; in others the reduction in bulk is moderate, and is compensated by increase in the intra- and extra-muscular fat (thus in stout children the atrophy of severe poliomyelitis may be quite masked to the eye); in still another category the increase in connective tissue with fatty accumulation overbalances the muscular wasting, and we have the pseudo-hypertrophic condition. Alterations in electro-muscular contractility are most important signs of impaired muscular innervation and nutrition. They present numerous and somewhat complicated variations of value for diagnosis and prognosis, but which cannot here be noticed at length. The general principle underlying these variations is this: that a muscle deprived of its normal innervation (centrifugal or motor) soon loses its capacity to respond to the induced (faradic) current, and reacts in an abnormal way to the galvanic current. This constitutes the reaction of degeneration of Erb.¹ The chief abnormality in the galvanic reaction of a paralyzed and diffusely atrophied muscle is its slow or wave-like contraction, which on a graphic, or even to the observer's eye, presents a striking contrast to the sharp, jerking, complete contraction of a healthy muscle. Besides, the reactions to the two poles become equal, or even reversed, so that we may obtain in testing by the polar method such formulas as $CaCC = AnCC$, or $CaCC < AnCC$. With reference to the failure of atrophied muscles to respond to the induced or faradic current, this qualification must be added: If the poles are applied on the moistened skin, as usual in testing or treating cases, no reaction occurs even with most intense currents; but if a needle be made one pole of the battery and inserted into the affected muscle, slight and limited contractions may be obtained with a moderate current for many months. Of this we have repeatedly satisfied ourselves in cases of poliomyelitis, lead paralysis, and traumatic peripheral paralysis. In the later stages of diffused paralytic atrophy, after an uncertain number of years, no reaction can be obtained with either electrical current. In fascicular non-paralytic muscular atrophy (as in progressive muscular atrophy) the loss of faradic contractility is only demonstrable in the affected fasciculi, good contractions being obtained in adjacent healthy fasciculi of the same muscle. The amount or extent of contraction varies *pari passu* with the progress of the atrophy. The galvanic reactions of this form of muscular atrophy are not yet well established. Muscles and muscular groups in a condition of impaired nutrition exhibit at an early period an interesting condition—viz. that they no longer contract by reflex excitation. Thus in a case of infantile poliomyelitis with paralysis of the muscles of the leg, these muscles no longer contract when the sole of the foot is tickled, and if the thigh-muscles are affected even so slightly as to appear of normal size and consistence, the patellar reflex is found wanting. In these and in traumatic cases the

¹ Conveniently expressed by the symbol *De R.*

reflex act is prevented by lesion of the centrifugal motor nervous apparatus, and perhaps also by the associated muscular trophic alterations.

Histological changes in atrophied muscles vary somewhat in character in different diseases, and vary much in degree at different periods of the atrophy. An early appearance is the presence of proteinaceous and of fatty granules or molecules in the sarcolemmal substance. Later, the muscular fibres become reduced in size, lose their striation, and show inequalities; the interstitial connective tissue becomes active and increases in amount, at the same time that fat is deposited. The fatty change in some cases, in others the granular or proteinaceous transformation, ultimately completely destroys the muscular substance, so that in the place of a muscle we find abnormal connective and fatty tissues, blood-vessels, fatty and proteinaceous debris, the whole presenting a pale yellowish-white aspect. It is in this final stage of degenerative atrophy that all electrical reactions are lost. In the pseudo-hypertrophic state the interfibrillary and interfascicular connective-tissue growth is much more active, and the wasting muscular fibres are buried in masses of wavy and fatty connective tissue. In this condition also electrical reactions may be wholly absent.

(b) Atrophy due to defective innervation sometimes affects the skin and bones. In the former, after nerve-injuries more especially, we observe loss of thickness, glossiness, and perverted circulation and secretion; the hairs may fall out or grow abnormally; the nails are slow of growth, thick, rugose, incurvated, and brittle. In other cases, as in cerebral and spinal paralyses, the skin of the paralyzed part is abnormally dry, rough, and furfuraceous, and it loses its elasticity. In some varieties of so-called skin diseases the patches of altered nutrition (eczema, bullæ, herpes, psoriasis, leucoderma, scleroderma, etc.) are often, probably, dependent upon nervous lesions.

In the very rare disease known as progressive facial atrophy the skin, subcutaneous areolar tissue, and the bones undergo extreme atrophy. The initial lesion is usually a patch of scleroderma with or without neuralgic phenomena; the skin is thin, darker and smoother than normal; it soon adheres to the subjacent bone (maxilla or zygoma), which itself steadily diminishes in size. Almost the entire half of the face (including the palate and tongue) may ultimately show the atrophic changes. We are not yet prepared to state the causal nerve-lesion in this disease.

The bones are abnormally fragile (*fragilitas ossium*) in some nervous diseases, more especially in dementia paralytica and posterior spinal sclerosis; but whether this condition is due directly to the nervous disease or is the expression of more general malnutrition is now undecided.

The complex lesions of joints observed in the course of posterior spinal sclerosis, the spinal arthropathies of Charcot, probably belong to this category. The affected joint (knee, shoulder, or ankle) rather suddenly swells, and the swelling usually invades the rest of the member or extends to the next distal joint; it is a hard, semi-elastic swelling unlike common oedema. After its gradual subsidence it is found that changes have taken place in the articulation itself, and later distinct evidences of destructive disease, such as erosion of cartilages, relaxation of ligaments, swelling, are observed. In many cases extra-articular lesions appear in the shape of osteophytic formations from the adjacent bones. The hydrarthrosis may persist or disappear. So complete may be the destruction of

the joint that—for example, in a case of arthropathy of the knee—the leg may be twisted about in all directions, and even over-extended so as to lie upon the anterior surface of the thigh. Examination of the joint post-mortem reveals non-suppurative destruction of all its component parts, cartilages, ligaments, and epiphyses; the eroded, deformed ends of the bones rub against one another in a false joint-cavity formed of the skin, connective tissue, tendons, and remains of ligaments. The absence of pain and tenderness in the course of arthropathies is a striking feature—so much so that when, in an adult patient, it is observed that manipulation or puncture of a diseased joint is painless, special inquiry should be made for symptoms of posterior spinal sclerosis.¹

(c) Under the head of degenerative atrophies should be included the secondary changes which affect certain nerve-tracts within the nervous system itself. It is impossible in this introduction to treat fully of this interesting category of trophic changes; the following summary must suffice: (1) When the cerebral motor cortex or any part of the associated pyramidal (or motor) tract is destructively injured, there occurs, in from three to six weeks, a degeneration of the whole tract caudad of (below) the brain. The myeline becomes granular and disappears, the cylinder-axes are broken up and vanish, the connective tissue (neuroglia) increases in amount; the atrophied and degenerated area appears in a trans-section rather translucent in contrast to the pearly white of the normal medullary tissue, and when the preparation is stained with carmine the patch takes up an abnormal amount of pigment. This is the so-called descending degeneration, or centrifugal atrophy of the central nervous system. (2) After total transverse lesions of the spinal cord, besides the above-described centrifugal degeneration caudad of the lesion, we observe frontad of (above) it similar changes in the posterior median columns, and in the direct cerebellar tracts—centripetal degeneration. At present we have no knowledge of centripetal (ascending) degenerations in the cerebrum and in nerve-trunks; and if the results of von Gudden's experimental method be cited against this statement, it must be replied that its effects are best seen in newly-born animals, and that its pathology is yet unknown. (3) Lesions of the anterior gray matter (ventral cornua) of the spinal cord, and of mixed nerve-trunks produce only centrifugal or descending degeneration. All the nerve-fibres deriving their innervation from the injured area in the cord, or in case of nerves all fibres below the injury, perish—*i. e.* their myeline breaks up and undergoes granular and fatty degeneration, their cylinder-axes are segmented and disappear, while at the same time the connective tissue of the nerve becomes abnormally active and increases. Furthermore, in cases of this category there are, inevitably, degenerative and atrophic changes in the attached muscles, and peculiar electro-muscular reactions (*vide supra*). All these central and peripheral nervous degenerations, due to a local lesion, are conveniently grouped under the name of Wallerian degeneration.

2. ERUPTIONS AND ULCERATIONS.—(a) The cutaneous eruption about whose nervous origin there is the least doubt is that known as herpes or

¹ We have known one case in which the diagnosis of *tubes dorsalis* was made (and verified after death) in this way, after the surgeon in charge of the patient had mentioned the fact that puncturing a swollen diseased knee-joint was painless.

zona. This manifests itself, with or without paræsthesiæ (pain, itching, formication, etc.), as vesicles upon deeply-inflamed spots of skin distributed in the territory of one or more sensory nerves, and almost always unilaterally. The destructive process in the derma is so profound as to leave scars which are indelible as a rule. In general terms it might be stated that herpes may occur in the range of any sensory nerve distributed to the skin or mucous membranes. The neuralgia attending its development may be severe, and in some cases lasts for years after the healing of the eruption. The pathology of this affection appears to be inflammation of the ganglion of the posterior root of one or more spinal nerves (including the trigeminus and glosso-pharyngeal) or of their trunks. Herpes may appear in the course of spontaneous and traumatic neuritis; and in the last-named conditions a variety of eruptions have been observed in the area supplied by affected nerves, such as eczema, bullæ, etc.

(b) That ulceration may result directly from a nervous lesion is shown by the history of herpes, where a destructive process takes place in the derma under such conditions as to exclude the action of external agencies. But the same cannot be said of the ordinary ulcerations and gangrenous lesions observed in a number of nervous diseases, as the bed-sores of myelitis or of spinal injuries, the ulceration of the cornea in trigeminal anæsthesia, the digital ulcers and gangrene of lepra, asphyxia of the extremities, and nerve-injuries. As regards all these, the proper explanation is, it seems to us, that the anæsthesia existing as a predisposing cause (leading to imperfect protection of the part), the ulceration itself, is directly, actively caused by external agencies. Let me briefly cite a few instructive experimental and pathological facts bearing on this question.

It is well known that in animals and man lesions of the trigeminus nerve sufficient to produce anæsthesia (of its first branch more especially) are frequently, if not invariably, followed by ulceration and perforation of the cornea and phthisis bulbi. These were long held to be true dystrophic changes, but about thirty and twenty years ago Snellen and von Gudden demonstrated independently and by different methods that these ocular lesions could be entirely prevented by absolute closure (perfect protection) of the eyelids prior to the experiment on the trigeminus. Not long afterward Brown-Séquard showed that the sloughing ulcers which occur about the foot of an animal whose sciatic nerve has been cut may be entirely prevented by care, cleanliness, and soft bedding. The conclusion to be drawn from these observations is that in almost all cases the ulcerations and sloughing observed in man during the course of a nervous disease sufficient to produce anæsthesia, such as traumatic neuritis, lepra anæsthetica, traumatic or simple myelitis transversa, disease of the trigeminal nerve, etc., are in reality produced by external agencies, injuries to the cuticle, action of filth, and, we think, the entrance of bacteria, which are well known to possess extraordinary powers of penetration into tissues whose protecting epithelial layer is removed. Clinical observation corroborates this view, for, with strict antiseptic treatment and under sealed dressings (collodion to ulcerated finger-tips), these ulcerations heal rapidly and completely, while the anæsthesia remains unchanged and the nervous lesions may even progress. At the same

time, while we believe the above to be the pathology of so-called trophic ulcers, we would admit the possibility of spontaneous neuritic ulceration and gangrene, as shown more especially in herpes.

3. ALTERED SECRETIONS.—Under the influence of disordered innervation secretions may be altered in quantity and in quality. Symptoms of this class may be caused by neural or by central lesions, and the mechanism of their action may be direct or reflex.

(a) After section or lesion by disease of the cervical sympathetic nerve we observe increased activity of the entire skin in the affected area of the head and face : there is more perspiration, lachrymation, and more cerumen is found in the ear. In cases of lesions of a certain part of the oblongata we find one result to be polyuria. In many cases of nerve-injuries the sweat-glands and hair-follicles of the parts supplied by the affected nerve appear to be sometimes abnormally active, or in other cases inactive. In some rare cases of insanity profuse salivation and extraordinary growth of hair are striking symptoms. Lastly, in some functional nervous affections the various secretions and excretions may be altered to extraordinary extremes (*e. g.* the polyuria and anuria of hysteria).

(b) Qualitative modifications of secretions also occur, as exhibited in the many variations in the composition of the urine in various neuritic conditions, the watery urine of hysteria, the phosphatic urine of neurasthenia. Injuries of a part of the floor of the oblongata (and very probably other lesions of the nervous system) give rise to the appearance of sugar, and sometimes of albumen, in the urine. Under the influence of disease or of an emotion the breast-milk may become toxic to the nursing child, causing diarrhœa, convulsions, etc. In some forms of nervous dyspepsia large quantities of acid or of alkaline fluid may be rapidly poured out into the stomach as a result of disturbed glandular and vasomotor action. In a few cases of neurosis malodorous or perfumed perspiration has been observed.

In a general way it may be stated that, inasmuch as the normal function of glands is largely, if not exclusively, under direct and reflex nervous control, their secretions may be quickly altered in quantity or quality by rapid nervous disease or by functional disorders. It is probable that much of our future progress in the semeiology of nervous diseases will be in this direction by the aid of improved medical chemistry.

4. ASSIMILATION, METAMORPHOSIS OF FOOD, TISSUE-LIFE, and BLOOD-MAKING are probably under nervous control to a certain extent, but our knowledge is not now in a state to speak positively and definitely of alterations in these processes as symptoms of nervous disease.

THE PRINCIPLES OF DIAGNOSIS.

HAVING in the preceding pages surveyed the field of neurological semeiology in an analytical way, it remains to briefly indicate how far and in what manner these data can be best utilized for logical diagnosis in the present state of science. If we may be allowed an illustration, we

would say that the foregoing sections contain a nearly complete vocabulary of the language of nervous diseases, and that the following pages express an attempt at formulating its grammar.

In the first place, it is important to classify the symptoms observed according to their probable immediate cause in the nervous organs, whether they are due to irritation or to the destruction of parts. The extreme value of such a distinction in practice was first emphatically brought forward by Brown-Séquard in his famous *Lectures on the Physiology and Pathology of the Central Nervous System* (Philada., 1860); and to the observance of this law of genesis of symptoms we believe that a large part of the subsequent extraordinary progress of neurological science is due.

The symptoms produced by irritation of nervous organs are usually hyperkineses or paræsthesiæ in their various forms. The symptoms, spasm, pain, or numbness, are usually, though by no means always, intermittent. That paralysis and anæsthesia may occur from irritation, by an inhibitory process, is not to be denied, yet we must maintain the extreme rarity of such a mechanism. The phenomena of inhibition are so prominent in the normal nervous system that a physician who looks at nervous diseases from the standpoint of the physiologist may well be excused for seeing morbid inhibitory processes where others do not.

The symptoms due to destructive lesions—*i. e.* those indicating destruction of parts of the nervous system—are paralysis, hyperkinesis, and anæsthesia, of absolutely or relatively constant presence. Thus, for example, the paralysis of common hemiplegia due to destruction of the motor part of the internal capsule is constant and permanent, while the accompanying tonic spasm (late contracture), which is considered an even more positive sign of serious destructive injury to the cerebral motor tract, is permanent, but intermittent—*i. e.* it is absent in profound sleep, and reappears as soon as the patient awakes.

The association of symptoms of irritation and those of destruction is frequent but variable. In many cases, as in cerebral tremor and posterior spinal sclerosis, spasm and paræsthesiæ precede paralysis, anæsthesia, and ataxia. In other cases (in many at a certain period) they coexist. In a small group of cases the irritative symptoms follow those indicating destruction, sometimes occurring years afterward, as in post-hemiplegic epilepsy and neuralgia due to cicatrices. We would repeat that very often, more especially in organic nervous affections, much light is thrown on the diagnosis by careful noting of the topographic distribution and chronological order of appearance of the symptoms.

In the second place, it is necessary to group the symptoms of disease of the nervous system in two great classes—*viz.* those representing demonstrable lesions, macro- or microscopic, and those dependent upon perverted functions or molecular malnutrition of the nervous organs or elements. The first group is designated as organic diseases; the second as functional affections. Mental diseases, so called, can also be classified, according to their symptoms, in either of these groups.

The symptoms of the first group, that of organic nervous diseases, are characterized by definiteness of distribution, by permanency, by relative invariability, and by the predominance of objective signs. Another important characteristic of organic diseases is their progressive or fatal

tendency, either with reference to life in general or to that of parts or organs. A third peculiarity of these diseases is that they do not occupy the patient's attention as strongly or as constantly as neuroses: in other words, the Ego is less involved.

The symptoms of the second group, that of functional nervous affections (neuroses and psychoses), are characterized by generality and indefiniteness of distribution, by relative variability, by easy removal or spontaneous disappearance, and by the preponderance of subjective symptoms. The affection may endure for many years or for a lifetime without fatal result and without special aggravation. The Ego is very strongly and deeply affected, fear, depression, and constant dwelling upon the symptoms being prominent features.

These are general statements intended to serve as guides for the preliminary study of a case. It must be remembered that they are all liable to exceptions, and that each patient must be separately considered. It should be borne in mind that what to-day appears as a functional affection, chiefly indicated by subjective symptoms, may in a few months present distinct signs of organic changes in the nervous system. Also, it must be added that in the present state of knowledge we sometimes are not sure as to the presence or absence of organic changes even after careful study of a case; as, for example, in some epilepsies and neuralgias.

Furthermore, allowance must be made for the following sources of error:

Anatomical variability; as, for example, in the distribution of peripheral nerves and in the amount of decussation of fibres of the pyramids;

The coincidence of diseases and multiplicity of lesions;

The toxic effects of drugs taken by the patient previous to our examination; as, for example, bromism.

I. The Diagnosis of Organic Diseases of the Nervous System.

This should invariably consist, in the observer's mind at least, of three separate diagnoses, each formed by the application of widely different sources of knowledge, and each requiring a different logical process. One diagnosis forms the indispensable preliminary to the others, and the last one, when correct, demonstrates that the neurologist is a physician as well as a specialist. A further utility of this procedure by the method of the threefold diagnosis is, in our opinion, that it constitutes the sure inductive reasoning to be employed in the search after the pathology of new diseases, and must prove of help in the future growth of neurological medicine.

These diagnoses are—

The diagnosis of the symptoms or symptom-group;

The diagnosis of the location of the lesion;

The diagnosis of the nature of the lesion or of the functional disorder.

1. The diagnosis of the symptom or symptom-group is to be made by—(a) careful inquiry into the manner of appearance, development, and chronological order of the symptoms as related by the patient or by his friends, and more especially by (b) an exact, and in some directions mi-

nute, determination of the symptoms, obvious or latent, present in the patient. This valuable method of exact observation is sometimes, no doubt, carried to a ridiculous extreme, entailing much loss of time without corresponding results; but in medical practice, as in all forms of professional work, there enters a sort of genius, partly innate, but largely developed by cultivation, which enables the observer to seize at once, apparently by intuition or in the course of a few minutes of study, the really valuable and suggestive phenomena; and it is in this line, the line of important and correlated facts, that observation cannot be too minute and exact. In following this method technical terms must be correctly used and definitions rigidly adhered to, as superficial and loose records nearly always mislead. Sometimes in the course of the examination a symptom is discovered or a hint is thrown out by the patient which suggests new lines of inquiry, and occasionally necessitates an entire rearrangement of the data obtained. Consequently, it is important that the observer should approach a case *tabula rasa*, and should, as far as possible, prevent his being biassed by anticipations of, and immature guesses at, the third or final diagnosis.

Besides exactness of observation, it is necessary that the physician should have a thorough knowledge of nervous nosology in order to complete the first diagnosis: he must be acquainted by book-study and by personal observation with the numerous types of symptom-groups which fill up our present classification of diseases, so that he can at once say, approximately at least, in what category the case before him belongs.

2. The second diagnosis, that of the location of the lesions, is to be arrived at by the application of the observer's knowledge of the anatomy and physiology of the nervous system; and therefore it is here that special training is of the greatest advantage. The anatomy and physiology of use in this connection are not the bare sciences as taught in ordinary text-books, but a higher sort of knowledge, corrected and extended by the teachings of pathology and pathological anatomy. The physician must be well versed in the recent revelations of experimentation and of autopsies bearing upon the architecture and functions of the central nervous system, and should be able to apply this knowledge deductively to the case in hand. In this manner the now abundant material grouped under the term *Localization of Cerebral and Spinal Diseases* (vide the next article) can be made of the greatest utility in every-day practice. The solution of the problem of localization of the lesion is much simplified if it be first accurately determined whether the lesion is peripheral, spinal, or cerebral.

3. The final diagnosis is with respect to the nature of the lesion. While the second diagnosis may be said to possess the greater scientific interest, this one must be admitted to possess paramount practical importance, as from it we derive the indications for rational treatment and the data of prognosis. The third diagnosis is to be made by the application of the observer's knowledge of general pathology and etiology; hence it is in this field that the best-trained physician succeeds—where the experienced practitioner may sometimes eclipse the brilliant specialist. The truth of this is maintained by those who hold, as we do, that it is unwise to embark in specialism without having had good hospital advantages and extensive general practice.

In order to arrive at the diagnosis of the nature of the lesion we must consider the family history, trace out predispositions, study the various causes of disease to which the patient has been exposed, and by a thorough examination of the various functions and the objective condition of the patient ascertain what pathological processes are active in him. Often the clue to the diagnosis is found in signs afforded by non-nervous organs, as nervous syphilis by nodes and cutaneous cicatrices, cerebral hemorrhage by renal disease and increased arterial tension, cerebral tuberculosis by pulmonary lesions, etc.

A purely empirical form of knowledge of some utility in proving the pathological diagnosis is that of the relative frequency of certain lesions in the two sexes, at different ages, in various professions, etc.—a statistical knowledge which is to be applied deductively to the case under study.

Considerable uncertainty sometimes remains even after the most careful analysis of a case, and often, after stating the first and second diagnoses quite positively, scientific caution and due regard for truth compel us to state the third diagnosis in alternative propositions or as a diagnosis of probability, to be finally settled by the appearance of new symptoms, or in some rare cases only by a post-mortem examination.

II. The Diagnosis of Functional Nervous Affections (Neuroses and Psychoses).

In some diseases of this class—as, for example, epilepsy—it is desirable to make the triple diagnosis as stated *supra*, but usually the two problems to be solved are—What is the symptom-group? and what is the pathology of the affection? The question of localization is less important and less easy of solution, as the symptoms are more usually generalized, often vague, and sometimes purely subjective.

1. The first diagnosis is to be made in the same manner as already stated, but besides, in many cases, a close psychological analysis is required to ascertain the emotional and mental state of the patient. Not only is this indispensable in cases of insanity, but it is often of great utility in other conditions, as hysteria, hypochondriasis, and simulation. In the course of this study we are frequently brought face to face with a most difficult problem—*viz.* the correct estimation of the degree of pain experienced by a patient. Is it a quasi-objective, correctly-portrayed sensation? is it magnified by abnormal sensitiveness or by true exaggeration? or is it simulated for a purpose? These questions demand the greatest freedom from prejudice and most delicate tact for their solution, and occasionally the most experienced physician is deceived. More especially are caution and scientific doubt to be exercised when this symptom (pain) stands alone or nearly so, as in some medico-legal cases and in certain hypochondriacal states where self-delusion seems to constitute the only real disease.

2. The diagnosis of the pathological nature of the functional disturbance (functional lesion) is to be made only by an exhaustive study of the patient's personal and family history and of his general condition. The following are the principal lines of inquiry to be followed :

(a) As to hereditary predisposition: direct or indirect inheritance of neurotic tendencies, of psychic peculiarities, and as to the presence of the various psychic and physical signs grouped under the term psychic degeneration.

(b) As to personal habits: overwork, masturbation, the abuse of tobacco, alcohol, or coitus, injudicious diet, abnormal postures, injurious avocations, etc.

(c) As to dyscrasic and hæmic conditions: uræmia, lithæmia, anæmia, malarial and syphilitic infection, etc.

(d) As to the condition of important organs: of the eye in connection with headaches and vertigo; of the ear in relation to vertigo and epileptiform attacks; of the heart (and arterial tension) in various head-symptoms; of the sexual organs in hysteria, hypochondriasis, epilepsy, etc.

A serious stumbling-block in this last line of inquiry is the ever-recurring question as to the causal relation between the symptoms observed. Is the asthenopia the cause of the headache, or does the neurasthenia, giving rise to the headache, cause the asthenopia? Does the extremely slow action of the heart in a given case produce the epileptoid attacks, or are both due to a lesion of the medulla? Does ovarian hyperæsthesia and neuralgia (with or without organic changes) cause the hystero-epilepsy, or is the ovaria one of the numerous peripherally projected sensory symptoms of the hysteric state? Does the lithæmia, oxaluria, azoturia, or phosphaturia found in a patient give rise to the nervous symptoms complained of, or are they (the morbid excretions) the result of defective innervation? The candid neurologist, looking at his cases from the standpoint of the general physician rather than from the loophole of narrow specialism, must admit that these questions vex him daily, and that they are often not to be resolved in the present state of knowledge except by a recurrence to the therapeutic test.

For this extremely difficult diagnosis of the pathology of functional nervous affections we would obtain much immediate assistance if observers had the courage to publish their cases in continuous series, instead of giving us successful cases, which often only serve to mislead. For example, how greatly would the question of the relation between ovarian symptoms and epilepsy (also hystero-epilepsy) be advanced if we had the final results of all cases of removal of the ovaries for these diseases at a period not less than one year after the operation! And so with the attempts made to cure headaches by the correction of errors of refraction and weakness of the interni. The profession has a right to demand a frank and full report of the experience of those who practice and teach in these directions.

THE LOCALIZATION OF LESIONS IN THE NERVOUS SYSTEM.

By E. C. SEGUIN, M. D.

THERE are two ways in which this important subject may be treated. Of these, the more interesting and logical would be to systematically expose the results of anatomical researches and of physiological experiments which tend to demonstrate the organic independence and the functions of various parts of the nervous system, and to give a classified series of results of autopsies bearing on localization. This would be all the more satisfactory because the questions involved, although of much importance in practice, are in reality physiological. The localization of functions being known, the physician could from the symptoms (*i. e.* perverted or abolished functions) present make a deductive diagnosis of great exactness. A treatise on medicine, however, cannot allow the space necessary for such a treatment of the topic which is best suited for monographic writing. The other method of exposition, the one we will follow, is that of summary statement of the association of the symptoms with definite lesions, with occasional anatomical and physiological explanations. This will, after all, be a series of diagnostic propositions stated as concisely and classified as practically as possible. With this end in view we divide the subject into five parts:

The localization of lesions in the peripheral nervous system (including the cauda equina);

The localization of lesions in the spinal cord;

The localization of lesions in the medulla oblongata;

The localization of lesions in the encephalon.

Cranio-cerebral topography.

I. Localization of Lesions in the Peripheral Nervous System.

In general terms, it may be said that lesions of peripheral (cerebro-spinal) nerves give rise to various sensory symptoms in the area of cutaneous distribution of the affected nerves, and to a flaccid atrophic paralysis in muscles supplied by the same nerves. These muscles almost always exhibit the De R. in varying degrees, and other trophic and vaso-motor symptoms are common. Many of these symptoms also occur in cerebral and spinal diseases, so that, after all, the diagnosis of peripheral localization depends largely on a correct knowledge of the course and distribu-

tion of nerves; of the relative distribution of the sensory and motor filaments of nerve-trunks; and of the frequent anomalies which occur. The subject of collateral innervation at the periphery must also receive attention, as involving a source of error.

Of extreme importance is the law of the relative distribution of motor and sensory filaments derived from one nerve-trunk. This, Van der Kolk's law,¹ has hardly received the attention it deserves from practical neurologists. Briefly stated, it is that of the two sorts of fibres in a mixed nerve the sensory filaments go to those parts which are moved by muscles innervated by the motor filaments of the same nerve. The reader can verify for himself the exactness of this law by making sketches of an extremity and tracing the motor and sensory distribution of its various nerves. There are partial and apparent exceptions to the formula, but this objection applies to almost all our medical laws. In the cranial system of nerves it is necessary to consider the trigeminus as the sensory companion of the six anterior motor nerves; the pneumogastric as the associate of the spinal accessory (in part).

(a) Irritative lesions of nerves, as tumors, punctured wounds, perineuritis, moderate pressure, etc., are indicated by pain, numbness, and other paræsthesiæ in their cutaneous distribution, and of spasm or cramp with paresis only, in the associated muscles. Pain is the most prominent symptom by far, and many cases of so-called neuralgia belong to this category. As a rule, there is no anæsthesia, and the electrical reactions of nerves and muscles remain normal, or at least they do not present De R. In some cases vaso-motor spasm (coldness, white or bluish appearance of parts) shows itself in the most peripheral distribution of the nerve. The cutaneous and tendinous reflexes are variable, but usually preserved.

(b) Destructive lesions of nerves, by section, severe pressure, true neuritis, etc., are characterized by anæsthesia with or without paræsthesiæ, by motor and vaso-motor paralysis, and by loss of superficial and deep reflexes. Later, there occurs degenerative atrophy of the paralyzed muscles with fully-developed De R., and dystrophic changes in the skin, etc. supplied by the sensory filaments of the injured nerve. In these anæsthetic parts ulceration is easily caused by traumatism and want of cleanliness.

The abnormal electrical reactions of the paralyzed muscles are of much importance for the diagnosis of the amount of injury done to the nerve and for the purpose of prognosis. They may be summarized as follows, assuming a case of complete section of a nerve-trunk:

a. The Faradic Reactions diminish rapidly in degree in both nerve and muscles from the third or fourth day, and in the nerve they are, as a rule, completely lost at the end of from ten to fifteen days. In the muscles complete loss of faradic reaction is noted only somewhat later, and is absolute. A return of musculo-faradic contractility is a most positive sign of recovery of the nerve.

β. The Galvanic Reactions.—In the nerve, distal of the lesion, the result is similar to that stated above—viz. after a few days (from five to fifteen) all reaction disappears. The anatomical cause of the complete

¹ Van der Kolk, *On the Minute Structure and Functions of the Spinal Cord, etc.*, p. 7, New Sydenham Soc. transl., London, 1859; Hilton, *On Rest and Pain*, p. 101, Am. ed., N. Y., 1879.

loss of the faradic and galvanic reactions in the nerve is its disintegration by the Wallerian degeneration. In the attached muscles the phenomena are widely different, and present interesting and complicated variations. In the first place, during a variable number of days there is increased excitability—*i. e.* the paralyzed muscles, deprived of innervation, contract to a much weaker current than do the homologous normal muscles. This is best shown in cases of peripheral facial paralysis (Bell's palsy) in the second and third weeks, by placing the electrodes in the median line, one upon the cervical vertebrae, the other (a small testing interrupting electrode) on the chin; on closing a very weak current of from four to eight elements it will be seen that the muscles on the paralyzed side of the face (the lower muscles) contract distinctly, while those on the normal side remain quiet. In the course of time, many weeks usually, the excitability diminishes, and falls below the normal, and in some cases ultimately disappears. These are known as the quantitative changes in musculo-galvanic reactions. During the long period preceding recovery, or without it, various qualitative changes are also observed in the reaction. The normal general formula of $\text{CaCC} > \text{AnCC}$ (with rapid, jerking and full contractions of the muscle) becomes $\text{CaCC} = \text{AnCC}$ or $\text{CaCC} < \text{AnCC}$. Often, too, distinct opening contractions occur, usually AnOC . The muscular contractions also tend to the tonic type or tetanus, expressed as CaDT or AnDT , etc.

The form of the contractions obtained is much altered. Throughout a practically endless period in some cases, or until regeneration of the nerve takes place in others, it is observed that musculo-galvanic contractions are delayed, are slower, less jerking, or assume an undulating wave-like character, easily passing into tetanus. This change from the rapid, jerky, and full normal muscular contraction to one which is slow and wave-like we consider to be the most positive and reliable evidence of neuromuscular degeneration and of the cutting off of the spinal-cord influence. Fig. 4 shows the characters of a human degenerative myogram contrasted with a normal one, Fig. 3.

In the period of recovery or regeneration of the nerve the musculo-galvanic reactions slowly reacquire their normal characters; the normal suddenness and completeness of the contractions gradually appear, and faradic excitation causes slight responses. Lastly, the nerve also begins to exhibit excitability under galvanism and faradism. These various abnormal electrical reactions, also frequently observed in diseases of the spinal cord, constitute the so-called reaction of degeneration, or De R. The subject is one of much practical importance, and for details the reader is referred to the treatises on electro-therapeutics of Erb and De Watteville.

Just as we depend upon the De R. to prove interruption of motor nerve-fibres (or, in other cases, destruction of ganglion cells in the anterior horns of the cord), so do we rely upon the demonstration of complete anæsthesia to prove interruption of sensory fibres. In seeking for the area of anæsthesia several points must be borne in mind: (1) The normal

FIG. 3.

Contraction of Normal Abductor Indicis, CaCC , with strong current (Amidon¹).

¹ "The Myography of Nerve-degeneration in Animals and Man," *Archives of Medicine*, viii., No. 1, 1882.

distribution of the principal nerve-trunks as taught by ordinary anatomical works ; (2) the remarkable anomalies of distribution which sometimes occur ; (3) that many nerves near their endings exchange filaments in very variable numbers ; loops for collateral innervation, which will supply some sensibility to parts which, judging by ordinary anatomical rules, should be made anæsthetic by section of a given nerve-trunk ; (4) another consideration is the degree of anæsthesia. Before pronouncing upon the complete and fatal division of a nerve-trunk (by injury or by disease), absolute anæsthesia should be demonstrated in its area of principal and isolated distribution. Ordinary tests are not, as a rule, sufficient for this purpose. The best means in our experience consists in the use of a very strong induction (faradic) current, as follows : The skin of the suspected

FIG. 4.

Contraction of Paralyzed Muscle on thirty-first day of Bell's palsy of the face. CaCC. 20 El. (Amidon). Shows retarded contraction and slow contraction, with tendency to tetanus.

region to be thoroughly dried and rubbed with chalk or powdered starch ; one pole, consisting of an ordinary wet electrode, to be applied just above the part to be tested, and the other pole, consisting of a single wire, with which different parts of the anæsthetic area are to be touched. By this means partially insensible regions, not responding to pricking and burning, may be made to yield reaction, and the area of absolute anæsthesia be thereby much reduced. Malingering may also be readily exposed by this test, which presents another advantage—viz. of not causing local injury or scars as burning will.

It follows from the preceding statements that in cases of limited atrophic paralysis with De R. the diagnosis between a central lesion (destruction of ganglion cells of the anterior horns of the cord) and a strictly peripheral (or neural) lesion is to be chiefly based upon two considerations : (1) The distribution of the paralysis, which in the first case affects muscles which are physiologically grouped or associated, while in the second case the simple law of anatomical associations or grouping is observed ; (2) by the state of sensibility, which is normal in disease of the anterior horns of the cord, and is frequently impaired or abolished in nerve lesions.

Lesions affecting the cauda equina cause all the above-mentioned symptoms of peripheral lesions in a limited (partial) paraplegic distribution. If the lesion or injury be in the sacro-coccygeal region, the symptoms will, as a rule, be found confined to parts below the knee, occasionally also involving the muscles on the posterior aspect of the thigh (flexors of the leg). Below the knees we find an atrophic paralysis with De R., anæsthesia of the foot and part of the leg, loss of plantar and achillis reflexes, and the sphincter ani will be paralyzed. The patellar reflex is

preserved or exaggerated. In case the lesion be in the lumbar region, below the first lumbar vertebræ, the symptoms will be found to extend as high as the groin, involving also the buttocks and sphincter ani; state of the bladder variable. All reflexes will be lost in the paralyzed extremities, except in some cases the cremasteric reflex.

Strange as it may appear, physicians do not always remember that there is practically no lumbar spinal cord (vide Fig. 2), and that injuries, etc. of the lumbar vertebræ and dura tend to affect nerves, and not a nervous centre.

II. Localization of Lesions in the Spinal Cord.

Diseases of the spinal cord are distinguished by the following general characters, positive and negative:

Positive Characters.—Tendency to primary bilateral or paraplegic distribution of all the symptoms. In the majority of cases preservation of electro-muscular excitability, and in one well-defined group of cases De R. more or less typically developed in the paralyzed parts. Frequent vesical and rectal paralysis, either of the retaining or of the ejecting apparatus. Pains and other paræsthesiæ in the extremities, the pains often possessing the electric or fulgurating character. Anæsthesia of paraplegic distribution. Sensations of constriction or cincture about a limb or about the body at various levels. Occurrence of ataxia without paralysis. Progressive muscular atrophy without actual paralysis. Easy production of eschars (bed-sores).

Negative Characters.—Absence of typical hemiplegic or monoplegic distribution of symptoms. Rarity of head symptoms, as headache, vertigo, mental disturbance; of lesions of the optic nerve. Absence of epileptiform convulsions. Absence of such grouping of motor and sensory symptoms as would exactly correspond to the area of distribution of one or more large nerve-trunks.

The above symptomatic indications are, of course, of the most general meaning only, and are liable to exceptions and subject to varying conditions.

The **DIAGNOSIS** of the exact localization of lesions in the spinal cord, considered from the clinical standpoint, is perhaps best arrived at by following an anatomical and physiological order of subdivision of the problem into three questions, as follows:

FIRST QUESTION.—BEING GIVEN SYMPTOMS INDICATING DISEASE LIMITED TO ONE OR MORE SYSTEMS OF THE SPINAL CORD, TO DECIDE WHICH ARE AFFECTED.

Physiology and the results of embryological and pathological researches justify us in making a general division of the spinal cord, for purposes of diagnosis, into two great systems, whose limits are fairly well known—viz. the *æsthesodic* or sensory system, and the *kinesodic* or motor system. The following outline diagram (Fig. 5) of section through the spinal cord exhibits the ascertained limits of the two systems.

A. Lesions of the *Æsthesodic* System.—Limits of the *Æsthesodic* System.—By this term we mean that combinations of ganglion-cells and nerve-fibres whose functions are locally sensory, and of those fibres which transmit impressions centripetally (frontad) to the encephalon. The

following are the recognized parts of this system, as outlined on the diagram: (1) the posterior (dorsal) nerve-roots and attached ganglia; (2) the posterior gray horn and central gray substance to an unknown distance ventrad; (3) the fasciculi cuneati (columns of Burdach), whose lateral parts are more particularly designated as posterior root-zones; (4) the fasciculi graciles (columns of Goll) or posterior median columns;

FIG. 5.

Diagram of a Transverse Section of the Spinal Cord through the Cervical Enlargement: The aesthesodic system is shaded, the kinesiodic system unshaded. Parts of the aesthesodic system: (1) Posterior nerve-roots; (2) posterior gray horns; (3) fasciculi cuneati (columns of Burdach, inclusive of posterior root-zones); (4) fasciculi graciles (columns of Goll or posterior median columns); (5) ascending cerebellar fasciculi; (6) columns of Clarke. Parts of the kinesiodic system: (7) Anterior roots; (8) anterior columns (inclusive of anterior root-zones); (9) anterior gray horns; (10) crossed pyramidal fasciculi; (11) direct pyramidal fasciculi (columns of Türeck); [10 and 11 are the intraspinal prolongation of the cerebral motor tract]; (12) lateral columns, of ill-defined limits and unknown functions; P. R., posterior roots; P. S., posterior septum; A. R., anterior roots; A. F., anterior fissure.

(5) the fasciculi ad cerebellum; (6) the vesicular columns of Clarke (most developed in the dorsal part of the cord). All of these parts have sensory functions, or at least transmit impressions centripetally, and they undergo secondary (Wallerian) degeneration toward the encephalon—*i. e.* frontad of a transverse lesion of the cord.¹

At the present time there is only one lesion of the aesthesodic system which can be diagnosed during the patient's life from positive symptoms.

(a) Lesions of the fasciculi cuneati (posterior root-zones, 3). The symptoms of lesion (usually sclerosis) in this region are wholly sensory

¹ There are some results of physiological experiments and a few isolated pathological facts which would seem to point to the existence of other sensory (centripetal) fasciculi in the lateral columns, but it would be wholly premature to make use of these facts in a practical consideration of the subject.

and ataxic. At an early stage acute pains, fulgurating pains, occur in the extremities; later paræsthesiæ, anæsthesia, and ataxia. The fulgurating pains caused by the slowly-progressive lesion of the posterior root-zones are very peculiar, and almost pathognomonic (vide preceding article for their description). In some cases paræsthesiæ precede the pains, which inversion of the usual order must be due to a difference in the starting-point of the sclerosis within the large fasciculi cuneati. Tendinous reflexes (especially the patellar) are lost at an early period in the disease, and by noting the disappearances of the different reflexes we can trace with some accuracy the longitudinal extension of the sclerosis (vide Fig. 2). In many cases the pupillary reflex is also abolished, constituting the Argyll-Robertson pupil.

As negative characters of lesions of the posterior root-zones (and of the rest of the æsthesodic system) we note absence of paralysis, contracture, atrophy, and De R.

In the present state of our knowledge of spinal physiology and pathology we think that a lesion in this location should be recognized by the physician early and positively—in some cases years before ataxia and other grosser symptoms make the diagnosis of locomotor ataxia obvious even to a layman's eye.

(b) Lesions of the fasciculi graciles (column of Goll, 4) cannot, we believe, be recognized directly by positive symptoms. There are a few cases on record of primary (?) sclerosis of these columns, in which during life vague sensory symptoms had been noted, but we cannot build upon such data. Indirectly, however, we can in many cases diagnosticate degeneration of these fasciculi, reasoning from the data of pathological anatomy. Thus, for example, in advanced cases of sclerosis of the fasciculi cuneati (posterior spinal sclerosis) we know that in the dorsal and cervical regions of the cord the columns of Goll are in a state of secondary degeneration. After complete transverse division of the cord by injury, extreme pressure, or focus of myelitis, etc. the same (centripetal) degeneration exists above the lesion.

The same remarks apply fairly to our clinical knowledge of the remaining parts of the æsthesodic system, columns of Clarke (6), and fasciculi ad cerebellum (5). We know absolutely nothing of lesions of the posterior horns (2) in their clinical and diagnostic relations.

B. Lesions of the Kinesodic System.—Limits of the Kinesodic System.—In general this includes the antero-lateral parts of the cord. In a trans-section of the cord (vide Figs. 5 and 6) the following columns and fasciculi are recognized, their location and limits being made known to us by embryology, descriptive and pathological anatomy: (7) The anterior (ventral) nerve-roots emerging from (8) the true anterior columns or anterior root-zones; (9) the ventral (anterior) gray horns with their groups of ganglion cells; (10) the crossed pyramidal fasciculus, which is the caudal continuation of the cerebral motor tract of the opposite hemisphere; (11) the direct pyramidal column (column of Türek), which is the caudal continuation of the cerebral motor part of the hemisphere on the same side; (12) the antero-lateral column. Fasciculi 10 and 11 bear an inverse relation to each other—*i. e.* 11 is larger in proportion as 10 is smaller.

In a general way it may be stated that lesions of the kinesodic system are characterized positively by the isolated existence or predominance of

motor symptoms, by impairment of muscular nutrition, and by De R.; also by contractures. The reflexes are almost never normal, being either exaggerated or lost. Negative symptoms are—absence of sensory symptoms, of ataxia, and of vesical or rectal symptoms.

(a) Lesions of the anterior gray horns (9) are revealed by most definite and characteristic symptoms. There occurs a flaccid paralysis involving more or less extensive groups of muscles in the extremities, rarely truncal muscles, and never those of organic life. In a few weeks the paralyzed muscles undergo atrophy, sometimes to an extreme degree, and various degrees of De R. are present. Cutaneous and tendinous reflexes

Diagram of a Transverse Section of the Spinal Cord through the Lumbar Enlargement: The aesthesodic system is shaded; the kinesodic system unshaded. Parts of the aesthesodic system: (1) Posterior nerve-roots; (2) posterior gray horns; (3) fasciculi cuneati (columns of Burdach, inclusive of posterior root-zones); (4) fasciculi graciles (columns of Goll, or posterior median columns); (5) ascending cerebellar fasciculi; (6) columns of Clarke. Parts of the kinesodic system: (7) Anterior roots; (8) anterior columns (inclusive of anterior root-zones); (9) anterior gray horns; (10) crossed pyramidal fasciculi; (11) direct pyramidal fasciculi (columns of Türek); (10 and 11 are the intraspinal prolongation of the cerebral motor tract); (12) lateral columns of ill-defined limits and unknown functions; P. R., posterior roots; P. S., posterior septum; A. R., anterior roots; A. F., anterior fissure.

are abolished. The bladder and rectum are normal. Sensory symptoms absent, and if present consist only of mild paræsthesiæ, which are probably due to postural pressure upon nerve-trunks or to disturbance of the peripheral circulation. There is no tendency to the formation of bed-sores, but circulation and calorification are reduced in the paralyzed members. It should be remembered that paralysis due to systematic lesion of the anterior gray horns is never typically paraplegic, with horizontal limit-line of sensory symptoms, a cincture feeling, and vesical paralysis.

The above symptom-grouping is characteristic of lesion of the anterior horns en masse; in other words, of poliomyelitis. In that form of systematic disease of the anterior horns which consists primarily and chiefly of a degeneration or molecular death of the ganglion cells there is no true paralysis; the atrophy of muscles is infinitely slower, and it proceeds in various muscles fasciculus by fasciculus, the wasting being usually preceded by fibrillary contractions, and being almost always symmetrically located on the two sides of the body (affecting analogous or homologous parts). The electrical reactions are abnormal, in that musculo-faradic reaction is lost in exact proportion to the wasting; so that in a large muscle one part may contract normally, while the adjacent fasciculi do not. It is as yet uncertain whether De R. occur in this disease (progressive muscular atrophy). Calorification and circulation are much less impaired than in poliomyelitis; the negative symptoms are much the same.

It is sometimes difficult to distinguish poliomyelitis from generalized neuritis. The diagnosis is to be made by the presence in the latter disease of marked sensory symptoms—neuro-muscular pains, numbness, slight anaesthesia—and by a grouping of symptoms coinciding with the distribution of nerve-trunks and branches. No assistance can be derived from electrical tests, as both diseases yield more or less typical De R.

(b) Lesions of the spinal pyramidal tract (of fasciculi 10 and 11) are followed by motor symptoms only—viz. paralysis and contracture—or, in other words, by a spastic paralysis. Sensibility is unaffected; the bladder, rectum, and truncal muscles are not distinctly paralyzed; the reflexes are much increased, and ankle-clonus is often present. The electrical reactions of the paralyzed muscles are normal, qualitatively at least. The diagnosis of localization may be pushed still farther by the following considerations:

(1) When the condition of spastic paralysis is unilateral, of hemiplegic distribution, and follows an attack of cerebral disease of some sort, we may feel sure that both the crossed and the direct fasciculi of the pyramidal (10 and 11) belonging to one cerebral motor tract are degenerated throughout the length of the spinal cord, the crossed fasciculus on the paralyzed side and the direct on the healthy side (same side as injured hemisphere). It would thus appear that lesion of the direct pyramidal fasciculus (11) produces no symptoms,¹ except, of course, in those rare cases in which it is larger than its associated crossed fasciculus.

(2) The above symptoms may be bilateral, as observed in children as a congenital or early-acquired condition. In such cases the four fasciculi of the motor tract are degenerated or undeveloped, in correspondence with a symmetrical bilateral lesion of the motor area of the cerebrum—imperfect development or early destruction.

(3) When the legs alone are the seat of spastic paralysis, with increased reflexes, spastic or tetanoid gait, without sensory symptoms, the diagnosis of a primary sclerosis of both lateral columns (inclusive of 10) of the spinal cord is justified.

(c) Lesions of antero-lateral columns of the cord (8 and 12), primary and independent of lesions of the anterior horns or of the crossed pyra-

¹ Unless it be the increase of reflexes which is so often observed on the non-paralyzed side in hemiplegics.

midal fasciculus, cannot now be diagnosticated during life. These large masses of fibres include fasciculi whose functions are probably motor; others (especially in 12) whose functions, according to recent experiments, may be sensory; and still others which are associating or commissural.

(d) Various combinations of the above lesions occur, and may be recognized positively during life: (1) Combined sclerosis of the posterior columns and of the crossed pyramidal fasciculi (3 and 10), indicated by ataxia with paralysis, absence of patellar reflex, tendency to contracture, pains, and anæsthesia less marked than in typical posterior spinal sclerosis. This symptom-group is usually found in children; it is pre-eminently a family disease, and is known as Friedreich's disease. Similar cases also occur in adults as a strictly personal disease. (2) Secondary degeneration of the pyramidal tract (10 and 11), with more or less localized atrophy of cells in the anterior horns (9) coexists in two forms: First, in a few cases of cerebral hemiplegia with contracture, and pathological atrophy of various muscles on the paralyzed side; second, as a distinctly spinal bilateral affection, characterized by a spastic or tetanoid state of the lower extremities, and a mixture of atrophic paralysis (*vide (a)*), with contracture in the arms and hands. This latter form is the amyotrophic lateral sclerosis of Charcot.

SECOND QUESTION.—BEING GIVEN SYMPTOMS INDICATING A TOTAL TRANSVERSE LESION OF THE SPINAL CORD, ONE INVOLVING ITS VARIOUS SYSTEMS AT A CERTAIN LEVEL, TO DETERMINE THE ELEVATION OR FRONTO-CAUDAL SITUATION OF THE LESION.

This question is usually easy of solution by the following method: Since a transverse lesion of the spinal cord gives rise to both motor and sensory symptoms of horizontal, paraplegic distribution caudad of the lesion, the first thing to do is to determine accurately the upper level of the symptom, either the line of anæsthesia or the limit of paralysis. The former is always much more definite than the latter, and usually serves as the guide to diagnosis, indicating accurately the uppermost part of the lesion. In the thorax the levels of sensory and motor symptoms nearly coincide, but in the extremities the operation of Van der Kolk's law of distribution of motor and sensory fibres of nerve-trunks must be borne in mind, although it does not apply as strictly in this case as in nerve lesions strictly speaking. Gowers's diagram will prove very serviceable in making a diagnosis of transverse lesions, and will also prove of use in the study of vertebral injury and disease, as it indicates with sufficient accuracy the relation between vertebræ (spinous processes) and segments of the spinal cord. (*Vide Fig. 2.*)

The following are the principal transverse localizations of disease which are usually recognized during life by the above procedure:

(a) Lesions of the cauda equina (by tumors, caries, or fracture of the bones, etc.) produce paralysis, anæsthesia, atrophy of muscles, with De R., in the range of distribution of the sciatic nerves mainly. The sphincter ani is paralyzed and relaxed, while the bladder remains normal as a rule. In all essential respects this paraplegiform, but not paraplegic, affection resembles that following injury to mixed nerve-trunks. It is in reality an intra-spinal peripheral paralysis. The more exact location of the lesion, in the absence of external physical signs (fracture, etc.), may be

approximately determined by a study of the distribution of the symptoms and their relation to nerve-supply.

(b) Lesions of the lower end of the lumbar enlargement, or *conus medullaris*, behind the first lumbar vertebra, will give rise to the same symptoms as (a). The expression, lumbar part of the spinal cord, should be more carefully used than it is at present in the discussion of spinal injuries and spinal-cord diseases, disease of the lumbar enlargement being common enough, but disease of the lumbar part of the cord very rare. In the discussion of railway cases, more especially, it is often forgotten that the spinal cord practically ends behind the first lumbar vertebra.

(c) Lesions of the middle and upper parts (segments) of the lumbar enlargement are evidenced by true paraplegia, without paralysis of the abdominal muscles. In some cases the quadriceps group, supplied by the crural nerve, is not paralyzed. The constriction and the limit of anæsthesia are about the knees, at mid-thigh, or near the groin in different cases. The paralyzed muscles, as a rule, retain their irritability and show normal electrical reactions; the cutaneous and tendinous reflexes are preserved or increased. The sphincter is usually paralyzed, while the bladder is relatively unaffected.

(d) Transverse lesion of the dorsal spinal cord produces the classical type of paraplegia—*i. e.* paralysis and anæsthesia of all parts caudad of the lesion. The limit of anæsthesia and the constriction band are nearly horizontal, and their exact level varies with the height of the lesion, from the hypogastric region to above the nipples. Below the level of anæsthesia, which indicates by the number of the dorsal nerve the upper limit of the cord lesion, there are complete paralysis, retention of urine, constipation with relaxed sphincter ani, greatly exaggerated reflexes in the lower extremities, even to spinal epilepsy; the muscles preserve their volume fairly well, and their electrical reactions are normal—sensibility in all its modes is abolished; bed-sores are easily provoked. Retention of urine is an early symptom in lesion of the middle dorsal region of the cord—sometimes, in our experience, preceding symptoms in the legs.

(e) A transverse lesion of the cord at the level of the last cervical and first dorsal nerves—*i. e.* in the lower part of the cervical enlargement—gives rise to typical paraplegia with a sensory limit-line at or just below the clavicle, but also with some very peculiar symptoms superadded. These characteristic symptoms are in the upper extremities, and consist of paralysis and anæsthesia in the range of distribution of the ulnar nerves. In the arms the anæsthesia will be found along the lower ulnar aspect of the forearm, the ulnar part of the hands, the whole of the little fingers, and one half of the annuli. There will be paralysis (and in some cases atrophy with *De R.*) affecting the flexor carpi ulnaris, the hypothenar eminence, the interossei, and the ulnar half of the thenar group of muscles, producing in most cases a special deformity of the hand known as claw-hand or *main-en-griffe*. Another important symptom of a transverse lesion in this location is complete paralysis of all the intercostal and abdominal muscles, rendering respiration diaphragmatic and making coughing and expectoration impossible. The breathing is abdominal in type, and asphyxia is constantly impending.

(f) A transverse lesion of the upper part of the cervical enlargement, below the origin of the fourth cervical nerve, gives rise to symptoms

designated as cervical or total paraplegia. The lower extremities and trunk are as in (d) and (e), but besides both arms are completely paralyzed and anæsthetic. The limit of anæsthesia usually extends along the clavicles to the acromion processes, or a little below, near the deltoid insertions. All reflexes caudad of this line are vastly increased, either with tonic or clonic contractions. In some cases of pressure upon the cervical cord by tumors, caries of vertebræ, etc. the tetanoid or spastic state of the extremities (the lower more especially) may precede paralysis for a long time; as the compression increases paralysis becomes more and more marked, while the reflexes remain high. This constitutes the clinical group we described in 1873 as tetanoid pseudo-paraplegia.

(g) Transverse lesions of the spinal cord from the decussation of the pyramids to the fourth cervical nerve are very rare, and usually of traumatic origin. They produce complete paralysis of the entire body, and also of the diaphragm (third and fourth cervical nerves), thus causing death by apnoea in a very short time.

(h) In ascending paralysis (Landry) the above symptom-groups, excepting (a), (b), are met with at successive stages of the disease, often by almost daily accession, until finally respiration ceases.

(i) The height of a transverse localized lesion (e. g. a stab-wound) of one lateral half of the spinal cord is to be determined by the various groupings of symptoms stated in the preceding paragraphs, the chief guide being the limit-line between the sensitive and anæsthetic portions of the body, measured vertically. The symptoms are, however, distributed in a very remarkable manner on either side of the median line. The paralysis will be found on the same side as the lesion, often accompanied by hyperæsthesia, vaso-motor paralysis, and loss of muscular sense, while the anæsthesia is on the other side of the body. When such a lesion occurs below the first dorsal nerve, the symptom-group is designated as hemiparaplegia; when the lesion is higher up, so as to paralyze the arms, the affection is termed spinal hemiplegia (Brown-Séquard).

Above the decussation of the pyramids total transverse lesions are practically unknown, so that the second question need not be followed farther.

By means of the data above given we are also enabled to determine the length—i. e. fronto-caudal extension—of the systematic lesions of the cord.

The symptoms of transverse lesions of the spinal cord are not exclusively caudad of the lesion, and some very striking ones are observable in the head. In lesions of the upper part of the dorsal cord and of the cervical enlargement (e, f, g) we observe vaso-motor and pupillary symptoms, due to injury of the spinal origin of the cervical sympathetic nerve; the pupils are contracted; the cheeks and ears congested and unnaturally warm; the cutaneous secretions are increased. In other words, the symptoms about the head, frontad of the lesion, are the same as those we produce experimentally in animals by section of the cervical sympathetic or of the lower cervical cord. In hemi-lesion of the cord, in man as in animals, these symptoms are unilateral, on the same side as the injury.

Another point to be remembered in the study of transverse lesions of the spinal cord is that the lesion may involve enough of the anterior

gray horns to give rise to atrophic paralysis with De R. in some few muscles deriving their motor innervation from the focus of disease. This is not rarely seen in cervical paraplegia.

THIRD QUESTION.—BEING GIVEN VERY LIMITED MOTOR OR SENSORY SYMPTOMS OF SPINAL ORIGIN, TO DETERMINE THE EXACT LOCATION OF THE FOCAL LESIONS CAUSING THEM.

(a) In the range of sensory disturbances this question rarely presents itself for solution. Localized anæsthesia and pain of spinal origin (except the fulgurating pains of tabes) are rare, and we do not know the relation of cutaneous areas with the spinal segments as well as we know the motor innervations. It should be stated here, however, that the location of a fixed pain and of a zone of anæsthesia is often of great value in determining what spinal nerve is affected, just outside of the cord itself, by such directly-acting lesions as vertebral caries, spinal pachymeningitis, tumors upon the spinal cord, etc. Among the various symptoms of Pott's disease of the spine, fixed pains in one side of the trunk, in one thigh, or in the upper occipital region, etc. is a sign against which the physician should always be on his guard, as it is a very early and valuable indication of the existence of an affection which requires special treatment as soon as a diagnosis can be made.

(b) Localized motor symptoms of spinal origin calling for a diagnosis of the focal lesions causing them are frequent, and are mostly met with in two affections—viz. progressive muscular atrophy and poliomyelitis. The problem is now capable in many cases of an approximately exact solution by the deductive application of our knowledge of the intimate connection between certain muscles and muscular groups and limited portions or segments of the spinal cord (anterior gray horns more especially). This knowledge has been accumulated and organized from ordinary anatomy, physiological experiments, and more especially from carefully-made autopsies with microscopic examination of the cord. We cannot present this subject better than by reproducing a tabular statement of these results prepared by M. Allen Starr.¹ Future autopsies may correct this table, and in making use of it the occurrence of anomalous nerve-distribution should be remembered:

LOCALIZATION OF FUNCTIONS IN THE VARIOUS SEGMENTS OF THE SPINAL CORD.

| Segment. | Muscles. | Reflexes. | Sensation. |
|----------|---|---|--|
| 2d-3d C. | Sterno-mast. trapezius . . . Scaleni and musc. of neck . . Diaphragm | Hypochondrium (?). | Neck and back of head. |
| 4th C. | Diaphragm Supra- and infra-spinatus . . Deltoid Biceps and coraco-brach. Supinator longus. Rhomboid. | Dilatation of pupil. . On irritation of neck . 4th-7th C. | Neck. Upper shoulder. Outer arm. |
| 5th C. | Deep muscles of shoulder-blade | Scapular 5th C.-1st D. | Back of shoulder and arm. |

¹ "The Localization of Functions of the Spinal Cord," *American Journal Neurology and Psychiatry*, iii., 1884.

TABLE (Continued).

| Segment. | Muscles. | Reflexes. | Sensation. |
|------------|---|--|--|
| 5th. C. | Deltoid | | Outer side of arm and forearm. |
| | Biceps and coraco-brach. | | Ant. upper two-thirds of arm. |
| | Supinator longus. Pectorales. Serratus magnus. | | |
| | Triceps | Elbow tendon. | |
| | Rhomboid, teres minor | 5th-6th C. | |
| 6th C. | Biceps, brach. antic. | | Outer side of arm and forearm. |
| | Pectorales | | Inner and front of forearm. |
| | Serratus magnus. Triceps. | | |
| | Extensors of wrist and fingers | Wrist tendons. | |
| | Flexors of wrist | Wrist tendons. | |
| 7th C. | Pronators, supinator brevis | 6th-8th C. | |
| | Triceps, long head | | Inner and back of arm and forearm. |
| | Extensors of wrist and fingers. Flexors of wrist and fingers | Palmar | Radial distribution in the hand. |
| | Pronators of wrist | 7th-8th C. | |
| | Subscapular. Latissimus dorsi. Teres major. | | |
| 8th C. | Extensors of thumb | | Forearm and hand, median and ulnar distribution. |
| | Flexors of wrist and fingers. Intrinsic muscles of hand. | | |
| 1st D. | Extensors of thumb | | Ulnar distribution to hand, little finger. |
| | Intrinsic muscles of hand. Thenar and hypothenar eminences. | | |
| 2d-12th D. | Muscles of back and abdomen | Epigastric } skin. { 4-7 D. Abdominal } { 7-11 D. | Skin of back and abdomen, and over upper gluteal region. |
| | Erector spinæ muscles | Hypochondrium (?). | |
| 1st L. | Ilio-psoas | Cremasteric | Skin over groin and front of scrotum. |
| | Sartorius | 1st-3d L. | |
| 2d L. | Ilio-psoas | Patellar tendon | Outer side of thigh. |
| | Sartorius | 2d-4th L. | |
| 3d L. | Flexors of knee, Remak (?) | Bladder and sexual centres. 2d-4th L. | |
| | Quadriceps femoris | | Front of thigh. |
| 4th L. | Adductores femoris. | | |
| | Adductores femoris | Rectal centre | Inner side of thigh and leg to ankle. |
| | Extensores femoris | 4th L.-2d S. | |
| | Tibialis anticus | Gluteal. | |
| | Peroneus longus | 4th-5th L. | |
| | Flexors of knee (Ferrier (?)). | | |

TABLE (Continued).

| Segment. | Muscles. | Reflexes. | Sensation. |
|----------|--|---------------------|----------------------------------|
| 5th L. | Outward rotators of thigh | | Lower part of gluteal region. |
| | Flexors of knee (Ferrier) | | Back of thigh. |
| | Flexors and extensors of toes. | | Leg and foot, outer part. |
| | Peronei. Muscles of calf of leg. | | |
| 1st S. | Muscles of calf of leg . . . | Foot clonus | Leg and foot, except inner part. |
| | Long flexor of great toe . . | Achillis tendon. | |
| | Intrinsic muscles of foot . . | Plantar. | |
| 2d S. | Intrinsic muscles of foot . . | Plantar | Perineum, anus. |

The above table should be studied in connection with Gowers's diagram of the vertebral column and spinal cord (Fig. 2, p. 53), for the thorough study of cases of neural and spinal localization. Additional details of much value with respect to the peripheral nerve distribution are accessible in the works of Ranney¹ and Ross.²

III. The Localization of Lesions in the Medulla Oblongata.

In general terms, lesions of the oblongata are characterized by the early appearance and prominence of motor symptoms in the mouth, throat, and larynx, and by bilaterality of the symptoms. Remote symptoms consist of disturbances in the cardiac action and in the functions of some intra-abdominal organs. There may also be more or less paralysis of all the extremities. These lesions may conveniently be classified, like those of the cord, into systematic and focal.

A. SYSTEMATIC LESIONS OF THE OBLONGATA.—1. Systematic lesions of the æsthesodic system of the oblongata are, for purposes of practical diagnosis, unknown at the present time.

2. Systematic lesions of the kinesodic system of the oblongata, on the other hand, are often positively recognizable during the patient's life.

(a) The most strictly systematic and most frequent of these lesions is that of secondary (Wallerian) degeneration of the pyramids, the prolongation of the cerebral motor tract. This morbid change gives rise to no distinct bulbar symptoms, and it can only be diagnosticated inferentially or inclusively by determining the existence of secondary degeneration of the entire pyramidal tract, from the occurrence of hemiplegia followed by contracture and increased reflexes. If the phenomena present be those of double spastic hemiplegia, there is surely degeneration of both pyramids.

(b) A systematic lesion affects the nuclei (origins) of the facial, hypoglossal, pneumogastric, spinal accessory, and the motor root of the trigeminal nerves, giving rise to a classical symptom-group. The symptoms thus produced are exclusively (?) motor and trophic, consisting of progressively increasing paresis, with atrophy of the muscles about the lips

¹ *The Applied Anatomy of the Nervous System*, N. Y., 1881, p. 355 *et seq.*

² *Handbook of Diseases of the Nervous System*, Am. ed., Philada., 1885, p. 356 *et seq.*

and cheeks, the intrinsic lingual muscles, the laryngeal and pharyngeal muscles. Later, the masseters, temporals, and pterygoids are sometimes involved; and, finally, extremely rapid action of the heart with pneumonic symptoms indicates the gravest extension of the morbid process. An early symptom in such cases is abnormal salivation. These affections, generally designated as varieties of bulbar paralysis, subacute or chronic, are usually readily recognized *intra vitam*, and recent discoveries in morbid anatomy have enabled us to correctly diagnosticate the seat of the lesion in its various extensions. The laryngeal paralysis represents disintegration (atrophy) of ganglion-cells in the bulbar origin of the spinal accessory nerve; lingual atrophic paralysis indicates the same lesion in the nuclei of the hypoglossal nerves; the labio-buccal symptoms are produced by lesion of the facial nerve nucleus (inferior facial nucleus of older writers); the paralysis of the muscles of mastication is due to extension of cell-degeneration to the motor nucleus of the trigeminus in the pons; and the final cardio-pulmonary symptoms indicate an extension of the lesion into the sensory (?) origin of the pneumogastric nerves.

It is evident that this systematic lesion of the oblongata is the equivalent or analogue of the various acute and chronic lesions of the anterior horns of the spinal cord, described *supra*; and in practice we sometimes find these bulbar and spinal lesions associated: progressive muscular atrophy of the extremities and amyotrophic lateral sclerosis being complicated with bulbar paralysis.

B. FOCAL LESIONS OF THE MEDULLA OBLONGATA, as at present known, occur mostly in the kinesodic system, but may also involve several fasciculi and nuclei at one time. The symptoms of such lesions are grouped in two principal types:

(a) Single symptoms, such as atrophy or atrophic paralysis of some one muscle or muscular group innervated by the hypoglossal, facial, or spinal accessory nerves. For example, unilateral atrophy of the tongue, when not due to neural injury, is quite surely the representative of destruction of one hypoglossal nucleus. It is possible that some cases of peripheral facial paralysis, so-called, or Bell's palsy, and cases of paralysis of the sterno-mastoid and trapezius, are not due to neural lesion, but to primary disease of the nuclei of the facial and spinal accessory nerves, either as poliomyelitis or as progressive cell-degeneration and atrophy.

A similar reserve must be used in speaking of the localization of small lesions in the oblongata, causing diabetes mellitus, polyuria, albuminuria, and salivation. From experiments upon animals and a few post-mortem examinations in human cases we know that such lesions may occur and cause the symptoms, but their recognition during the patient's life is at the present time next to impossible.

(b) The symptoms may be complex and belong to the general class of crossed paralysis, the mouth, face, tongue, and larynx being paralyzed (often with anæsthesia of the face) on one side, while the extremities are paralyzed on the other side. Such a symptom-group would indicate a large lesion (tumor) in one lateral half of the oblongata, more especially in its ventral aspect. These localizations will be studied more in detail farther on, under the general head of Crossed Paralysis due to Lesions of the Base of the Brain.

IV. Localization of Lesions in the Encephalic Mass.

Under this head, to prevent repetition and to facilitate condensation, we will consider the various localizations which can now be diagnosticated in the cerebrum, basis cerebri, and cerebellum.

It would be of the greatest advantage to preface these statements by a full summary of the anatomical and physiological data on which the localizations rest, but space is wanting for such an exposition, and the reader who is not already familiar with these branches of medical science will have to seek information in other accessible works.¹

In a general way, encephalic lesions are distinguished by the following :

Positive Characters.—Tendency to strictly hemiplegic or bilaterally hemiplegic grouping of symptoms; frequency of contracture or of a spastic state of the paretic muscles; increase of reflexes in the affected extremities; spasmodic manifestations in remote muscular groups, but not in areas of nerve-distribution (forms of Jacksonian epilepsy); the presence of paralytic and anæsthetic symptoms in the range of distribution of cranial nerves; frequency of neuro-retinitis or atrophy of the optic nerves; occurrence of lateral hemianopsia; production of symptom-groups known as varieties of crossed paralysis; frequency of head symptoms, as headache, vertigo, apoplectic and epileptic seizures; mental symptoms of various sorts, dementia, coma, etc.

Negative Characters.—Absence of truly paraplegiform distribution of symptoms, even when they are bilateral; of cincture feelings; of pain or other paræsthesiæ and anæsthesia in the distribution of nerve-trunks; of muscular atrophy and De R. in paralyzed parts. Rarely do we observe visceral paralysis and bed-sores.

Pathological localizations in the encephalon may conveniently be grouped under two heads—viz. systematic and focal lesions.

A. SYSTEMATIC LESIONS OF THE ENCEPHALON.—The recent advances of embryology, anatomy, physiology, and pathological anatomy have conclusively established the existence, and fairly well defined the limits, of a sensory (æsthesodic) and of a motor (kinesodic) tract in the brain; and certain lesions of these tracts produce such precise symptom-groups that their diagnosis during the patient's life is often possible, and that, too, with great exactness.

1. SYSTEMATIC LESIONS OF THE ÆSTHESODIC SYSTEM OF THE ENCEPHALON.—The limits of this system are as follows: Within the oblongata and pons it occupies a somewhat uncertain (from a clinical standpoint) location, its fasciculi and ganglia lying in a general way dorso-laterad of the motor or kinesodic system. In the crus cerebri the fibres of the sensory tract are more closely packed together, and constitute a dense fasciculus of white substance in the lateral part of the crus in its subcerebral extremity, estimated by Flechsig at about one-fifth of the entire crus, and thence it enters into the composition of what is known as the internal capsule. This narrow but all-important mass of

¹Ferrier, *The Functions of the Brain*, Am. ed., N. Y., 1876; Charcot, *Lectures on Localization in Disease of the Brain*, Am. ed., N. Y., 1878; Seguin, E. C., "Lectures on the Localization of Spinal and Cerebral Diseases," *N. Y. Medical Record*, 1878; Ranney, *Applied Anatomy of the Nervous System*, N. Y., 1881; Meynert, *Psychiatry: A Clinical Treatise on Diseases of the Fore-brain*, Part I., Am. ed., 1885.

white fibres, as revealed by a horizontal section of the hemisphere (vide Fig. 7), lies between the nucleus caudatus and the nucleus lentiformis, and between the latter and the thalamus, thus assuming a V or elbow shape. Of this, the caudal third of that part of the capsule behind the bend or angle contains all the sensory paths for the opposite half of the body, reinforced by paths for the special senses; it is the *carrefour* sensitif of French writers. From this region sensory fasciculi radiate to various parts of the cerebral cortex—in the parietal, temporal, and occipital gyri—in which physiological experiments and human cases of disease have shown sensory areas or centres. Of the fasciculi from special sense-organs which reinforce the internal capsule, the only one which is well defined and easily traceable is the fasciculus opticus (fasciculus of Gratiolet), derived in part directly from the optic tract of the same side and from the primary optic centres (lobus opticus, corpus geniculatum laterale, and pulvinar), proceeds, along with fibres of the internal capsule, dorso-laterad of the posterior cornu of the lateral ventricle, to the mesal aspect of the occipital lobe. A fasciculus from the olfactory apparatus doubtless also joins the internal capsule, but its course is unknown.

The following localization diagnoses are now possible in the *æsthesodic* system as above defined:

(a) A lesion of the internal capsule, just above the *crus cerebri*, involving its bend or knee and caudal segment, with or without injury to the nucleus lentiformis and thalamus, will give rise to the following symptoms: Complete typical hemiplegia and total hemianæsthesia on the opposite side of the body; the anæsthesia involves the special senses as well as the body. Vision is, however, unaffected, unless the lesion extend far enough back to involve the pulvinar and fasciculus opticus, when lateral hemianopsia occurs (dark half-fields on the side opposite the lesion). When this lesion is in the left hemisphere, sensory aphasia also occurs.

(b) A lesion involving the caudal part of the thalamus and of the internal capsule. With such a lesion the motor symptoms consist in transient paralysis, with usually persistent post-paralytic chorea or ataxia. The sensory symptoms are more marked, and resemble those produced by lesion (a). It may be determined with some degree of accuracy whether the lesion be in the thalamus border, or in the internal capsule near to the nucleus lentiformis by the absence in the latter case of lateral hemianopsia.

The topography of such lesions is illustrated by Fig. 7.

(c) Lesions of cortical areas connected with fasciculi of the sensory part of the internal capsule (c. i. 5).

(a) Lesion of the cortical area or centre for smell cannot at present be diagnosticated. From the results of experiments upon higher mammals we would expect such a centre to be in the cortex of the mesal gyri of the temporal lobe.

(β) Lesions of the cortical centre for taste are equally unknown; it is probably situated in the meso-basal aspect of the temporal lobe.

(γ) Lesions of the acoustic centre are somewhat better known, at least as far as the function of hearing language-sounds (psychic hearing) is concerned. A number of recently-published cases¹ have quite positively

¹ R. W. Amidon, "On the Pathological Anatomy of Sensory Aphasia," *New York Medical Journal*, xl. 113, 181.

shown that the existence of word-deafness indicates a destructive lesion of the dorsal gyri (more particularly the first and second) of the temporal lobe (the left always?). The lesion may also be in the inferior parietal lobule and gyrus supramarginalis, penetrating deeply enough to injure the acoustic fasciculus on its way from the internal capsule to the centre.

(d) The centre for visual impressions is now the best known of any of the sensory cortical areas. The experimental studies and pathological

FIG. 7.

Horizontal Section through the Centre of the Right Cerebral Hemisphere: M, median line; Nc, nucleus caudatus; Nucleus lent., nucleus lentiformis with its three segments; To, thalamus opticus; c. i., internal capsule with its frontal division, its bend or knee, and its caudal division. 1, mass of fibres destined for pons and others forming a part of the corona radiata, non-pyramidal fibres; 2, knee of the internal capsule, containing fasciculus from cortical centre for the face to the nucleus of facial nerve (non-pyramidal fibres); 3, fasciculus for the tongue and throat to nucleus of hypoglossus, etc. (non-pyramidal fibres); 4, fasciculi from the pre- and postcentral gyri and the paracentral lobule to the pyramid of the oblongata (the true pyramidal fasciculus, continued in the cord as fasciculi, 10 and 11 of Figs. 5 and 6); 5, the caudal third of the internal capsule, containing fasciculi destined to the sensory cortical centres.

results of the last few years have indicated that the occipital lobe was probably the seat of higher, organized vision (for form and color). More recent autopsies and re-examination¹ of the subject point to the cuneus and adjacent gray matter as the visual centre. The anatomical arrangement is, however, peculiar and complex, in that each cortical visual area receives impressions from one lateral half of both retinae, through the fasciculus opticus.

Destructive lesion of one visual centre is therefore indicated during

¹ E. C. Seguin, "A Contribution to the Pathology of Hemianopsia of Central Origin (Cortex-hemianopsia)," *Journal of Nervous and Mental Diseases*, 1886, No. 1.

life by the symptom lateral hemianopsia alone (the dark half-fields on the side opposite the lesion).

The accompanying diagram illustrates the course of the visual paths from the eyes to the cortical centres, and the mechanism of production of various forms of hemianopsia:

FIG. 8.

Diagram of Visual Paths, designed to illustrate specially Left Lateral Hemianopsia from any lesion—*L. T. F.*, left temporal half-field; *R. N. F.*, right nasal half-field; *O. S.*, oculus sin.; *O. D.*, oculus dexter; *N. T.*, nasal and temporal halves of retina; *N. O. S.*, nervus opticus sin.; *N. O. D.*, nervus opticus dext.; *F. C. S.*, fasciculus cruciatus sin.; *F. L. D.*, fasciculus lateralis dext.; *C.*, chiasma, or decussation of fasciculi cruciati; *T. O. D.*, tractus opticus dext.; *C. G. L.*, corpus geniculatum laterale; *L. O.*, lobi optici (corpus quad.); *P. O. C.*, primary optic centres, including lobus opticus, corp. genic. lat., and pulvinar of one side; *F. O.*, fasciculus opticus (Gratiolet) in the internal capsule; *C. P.*, cornu posterior; *G. A.*, region of gyrus angularis; *L. O. S.*, lobus occip. sin.; *L. O. D.*, lobus occip. dext.; *Cu.*, cuneus and subjacent gyri, constituting the cortical visual centre in man; The heavy or shaded lines represent parts connected with the right halves of both retinae. The reader may place the lesion as he pleases.

The following diagnostic propositions are applicable to cases presenting the symptom lateral hemianopsia :

"1. Lateral hemianopsia always indicates an intracranial lesion on the opposite side from the dark half-fields.

"2. Lateral hemianopsia, with pupillary immobility, optic neuritis, or atrophy, especially if joined with symptoms of basal disease, is due to lesion of the tractus opticus or of the primary optic centres on one side.

"3. Lateral hemianopsia, or sector-like defects of the same geometric order, with hemianæsthesia and choreiform or ataxic movements of one-half of the body without marked hemiplegia, is probably due to lesion of the caudo-lateral part of the thalamus or of the caudal division of the internal capsule (vide Fig. 7).

"4. Lateral hemianopsia, with complete hemiplegia (spastic after a few weeks) and hemianæsthesia, is probably caused by an extensive lesion of the internal capsule in its central and caudal part.

"5. Lateral hemianopsia, with typical hemiplegia (spastic after a few weeks), with aphasia if the right side be paralyzed, and with little or no anæsthesia, is quite certainly due to an extensive superficial lesion in the area supplied by the middle cerebral artery; we should expect to find softening of the speech-centre, of the motor zone and of the gyri lying at the extremity of the fissure of Sylvius—viz. the gyrus supramarginalis, inferior parietal lobule, and gyrus angularis. Embolism or thrombosis of the middle cerebral artery would be the most likely pathological cause of the softening.

"6. Lateral hemianopsia, with moderate loss of power in one-half of the body if associated with impairment of muscular sense, but without ordinary anæsthesia, would probably be due to a lesion of the inferior parietal lobule and gyrus angularis, with their subjacent white substance, penetrating deeply enough to sever or compress the optic fasciculus in its way caudad to the visual centre.

"7. Lateral hemianopsia, without motor or common sensory symptoms; this symptom alone, is due, we believe from the convincing evidence afforded by Cases 28, 29, 41, and 45, to lesions of the cuneus only, or of it and of the gray matter immediately surrounding it on the mesal surface of the occipital lobe in the hemisphere opposite the dark half-fields. Most surgical cases of lateral hemianopsia come at once or after convalescence within this rule, or No. 6."¹

The cortical visual area, as above defined, is supplied by one large vessel—viz. the occipital artery, a branch of the posterior cerebral. Embolism or thrombosis of the former vessel is to be thought of as the probable cause of a suddenly-developed lateral hemianopsia without paralysis or anæsthesia.

(ε) The cortical centre for sensory impressions of muscular sense, so called, is probably located in the inferior parietal lobule. The diagnosis of a lesion so placed, in a case presenting along with other sensory or with motor symptoms marked impairments of muscular sense in the arm and leg of one side, is justified by a few recent cases.² Spitzka

believes that he has clinically and pathologically demonstrated a basal path (fasciculus) for this mode of sensibility in the pons and oblongata, dorsad of the pyramidal tracts.¹

(ζ) Lesions of the cortical area for common cutaneous sensibility cannot be positively recognized at the present time. By exclusion of the better-known centres, and from experimental data, we may approximately locate it in the gray matter lying ventrad of (below) the inferior parietal lobule, extending to the base, and possibly the mesal aspect, of the temporal lobe, and possibly also on the lateral aspect of the occipital lobe.

2. LESIONS OF THE KINESODIC SYSTEM OF THE ENCEPHALON.—The kinesodic system is far better understood, anatomically and physiologically, than the æsthesodic. Its limits, beginning from the junction of the cord and oblongata, are as follows: The pyramids, containing the fibres of the direct and crossed pyramidal fasciculi of the cord (Fig. 5, Nos. 10 and 11), form the meso-basal aspect of the oblongata, appearing on either side of the median line as two large distinct bundles of white substance which enter the pons under its projecting transverse fibres. Within the pons each pyramid is divided into quite a number of fasciculi more or less separated by fibres of other systems. Again collected, these bundles constitute a considerable part of the crus cerebri—its basal middle two-fifths. (The outer or latero-dorsal one-fifth part of the crus belongs to the æsthesodic system, the middle (intermediate) two-fifths are the pyramidal fibres, and the remaining two-fifths, meso-basal part, contain some fibres from the direct cerebral motor tract destined for the hypoglossal and facial nuclei, and also large bundles probably derived from the nucleus caudatus and frontal lobes). As the crus enters the cerebrum and becomes what we know as the internal capsule, the pyramidal fibres occupy the bend or elbow of the capsule and part of its caudal segment (vide Fig. 7).

From this level the fibres of the internal capsule again diverge, as fasciculi whose physiological independence has been well determined, going dorsad and frontad to certain gyri of the cerebral cortex where their fibres join ganglion-cells. Three large fasciculi and corresponding cortical areas are recognized as constituting the pyramidal tract, strictly speaking: (1) A fasciculus which extends frontad to the base of the second frontal gyrus where it coalesces with the precentral, the centre and fasciculus for movements of the facial muscles of the opposite side; (2) a fasciculus which extends to the precentral and postcentral gyri, more especially in their middle part, constituting the centre and fasciculus for movements of the arm and hand; (3) another fasciculus which goes dorso-mesad, almost vertically in the brain, to join the ends of the pre- and postcentral gyri at the top of the hemisphere, and their continuation upon its mesal aspect known as the paracentral lobule, centre and fasciculus for movements of the opposite foot and leg. Besides these three great cortical areas and their connected fasciculi of nerve-fibres, which go to make up the pyramidal tract, we recognize (4) a cortical centre for speech movement of the tongue and lips in the base of the left third frontal gyrus over the fissure of Sylvius (Broca's speech-centre), with a connected white fasciculus which passes into the elbow of the internal

¹Spitzka, "A Contribution to the Morbid Anatomy and Symptomatology of Pons Lesions," *American Journal of Neurology and Psychiatry*, ii. p. 617 (1883).

capsule, and can be traced (by means of secondary degeneration) into the inner part of the base of the crus and into the pons, but not to the pyramid. Another probable centre (5), for coarse lingual movements

Fasciculi of sensory tract in full lines, to temporo-parieto-occipital convolutions: *n, c*, nucleus caudatus; *n, l*, nucleus lentiformis; *t, o*, thalamus opticus. 1, level of crus cerebri; 2, level of pons; 3, level of oblongata. (This diagram is to be used in conjunction with Fig. 7.)

and for the various movements of deglutition, is in the folds of the insula, its fasciculus not joining the pyramid.

The location of two other motor centres—one for the movement of the eyeballs in or near the gyrus angularis, and one for vocal laryngeal movements in the base of the right third frontal gyrus (homologous to the speech-centre in the left hemisphere), is problematical, or at least not well enough established to be recognized in a practical treatise.

Recent experimental researches have shown that to electrical excitation at least the fasciculi for the tongue, face, arm, and leg yield the same distinct reaction (isolated muscular contractions) as do their respective centres or cortical areas; perhaps they are more excitable.

When these cortical areas are destroyed by disease, or when their connected fasciculi are severed, secondary degeneration takes place and extends to the end of the respective bundles, even to the lower extremity of the spinal cord.

Before leaving the subject of the composition of the kinesodic system it is desirable to add a few words concerning the decussation of the pyramids or distribution of the pyramidal tract in the spinal cord. As is well known, this is double, a small part of the pyramidal bundle remaining on the same side of the median line, the so-called direct pyramidal fasciculus or column of Türek (Fig. 5, No. 11) forming the mesal edge of the anterior column of the cord. The larger part of the pyramid crosses the median line at the decussation, and enters the opposite lateral half of the cord, in which it is found as the crossed pyramidal fasciculus (Fig. 5, No. 10) in the posterior part of the lateral column, rapidly diminishing in size in the dorso-lumbar part of the cord. The

important point to bear in mind for the study of monoplegias and of hemiplegia is that the amount of decussation is far from uniform. This variability was first demonstrated by Flechsig.¹ He found in a series of sixty fetuses such variations in the relation of the crossed and direct fasciculi as 100 : 0 (complete decussation), 92 : 8, 84 : 16, 70 : 30, 52 : 48 (nearly semi-decussation, producing equal fasciculi), 35 : 65, 10 : 90 (almost non-decussation).

It should also be added that quite certainly the cerebellum, nucleus caudatus, nucleus lentiformis, and nucleus pontis form parts of the complete kinesodic system, but we are as yet ignorant of their exact connections and functions.

With respect to the anterior part of the frontal lobe, forward of the oblique line A B across Figs. 10 and 11, the study of human cases of destructive injury and disease would indicate that it is not associated either with the kinesodic or with the æsthesodic systems.

The SYMPTOMS of lesions of the kinesodic system, particularly of the pyramidal tract, are exclusively motor, consisting of spasm and paralysis. Contracture of the paralyzed parts follows the paralysis after a few weeks if the lesion be a destructive one.

Clinically, the following DIAGNOSES of localization of lesions in this system are now possible:

(a) Lesion of the speech-centre (4) and of its associated white fasciculus is indicated by intermittent or constant aphasia of the motor form, with or without paralysis of the face and limbs (on right side usually).

(b) Lesion of the facial centre (1) and of its associated fasciculus is characterized by the occurrence of spasm or paralysis, or of both in rapid succession, in the facial muscles; their electrical reactions remaining normal.

(c) Lesion of the brachial centre (2) and of its associated fasciculus is made known by spasm or paralysis, or by both in succession, in the hand and arm. In many cases (tumor especially) the first symptom is clonic convulsive movements of two or more fingers, extending to other parts of the arm. Such brachial monospasm or monoplegia is usually accompanied or followed by incomplete hemiplegia.

(d) Lesion of the crural centre (3) in the paracentral lobule and of its associated fasciculus of white substance is indicated by priority and predominance of convulsive and paralytic phenomena in the foot and leg: a crural monospasm or monoplegia exists with or without incomplete hemiplegia.

The positive diagnosis of these separate localizations is most feasible in cases of tumors or of cranial injury where the initial lesion is limited in extent and where the morbid process is for a time localized. As a rule, localized spasm (Jacksonian epilepsy) without loss of consciousness is the first symptom, followed after a time by localized paralysis (always in the same muscular groups); and later still the symptom-group becomes obscured by the supervention of other symptoms indicating extension of disease to other parts of the kinesodic system, or even to the æsthesodic system.

(e) Lesion of the insula and adjacent white substance laterad of the nucleus lenticularis (5) may be suspected from the rapid or sudden development of symptoms imitating those of acute bulbar paralysis, but with-

¹ *Die Leitungsbahnen im Gehirn und Rückenmark des Menschen*, Leipzig, 1876.

out bilateral paresis of the body and anæsthesia. Aphasia is very apt to coexist with the bulbar symptoms if the lesions involve the left insula, whose frontal folds are continuous with the speech-centre.

Common hemiplegia with contracture, but without anæsthesia, represents a gross lesion of the kinesodic system, involving several cortical centres or the motor part of the internal capsule:

(1) A widely-spread lesion of the cortex of the brain, softening of the motor zone (centres 1, 2, 3, 4) from embolism or thrombosis of the middle cerebral artery.

(2) Hemorrhage from vessels of the nucleus caudatus and nucleus lentiformis compressing or destroying the motor segment of the internal capsule at various levels. More rarely there is a form of softening or gliomatous growth involving the same parts. Any of these lesions may be so localized as to destroy only one fasciculus of the capsule, giving rise to monoplegia.

The limits of the so-called sensory and motor centres or cortical areas, and the possible localization of lesions in them, will be better understood by the help of the accompanying diagrams (Figs. 10 and 11, p. 90) of the lateral and mesal aspects of the hemisphere.

B. FOCAL LESIONS OF THE ENCEPHALON.—1. FOCAL LESIONS OF THE CEREBRUM, OF ITS CORTEX AND SUBJACENT WHITE SUBSTANCE, AND BASAL GANGLIA.—(a) Focal lesions of the frontal lobe produce no specific symptoms, and cannot be directly diagnosticated unless they extend as far caudad as the base of the second and third frontal gyri. The forward mass of the frontal lobe, including the orbital lobule (vide Fig. 10), appears to be inexcitable and insensitive. Even psychic symptoms do not necessarily appear after the loss of considerable amount of cerebral substance from this region. The diagnosis of tumors, abscesses, etc. in this part of the brain must be made by taking into consideration the seat of pain, the presence of cicatrices or other etiological indications, the general signs of the cerebral irritation and compression, but, after all, usually by exclusion. In some cases unilateral anosmia is produced.

(b) Focal lesions of the caudal part of the frontal lobes, of the insula, the pre- and postcentral gyri, and other parts of the motor zone are usually easy of diagnosis. The symptoms of such lesions have already been detailed when speaking of lesions of the kinesodic system.

(c) Focal lesions of the parietal, temporal, and occipital lobes of the brain have the characteristic semeiology of lesions of the æsthesodic system, considered supra.

(d) Lesions of the so-called basal ganglia, the nucleus caudatus, nucleus lentiformis, and thalamus, usually give rise to motor and sensory symptoms indirectly by pressure upon or destruction of the segments of the internal capsule which lie between these bodies (vide Figs. 7 and 9). Lesions of the nuclei caudatus and lentiformis are thus more prone to produce purely motor symptoms, while sensori-motor and ataxic symptoms result from lesion of the thalamus.

The symptoms indicating lesions strictly limited (in extent and in effect) to these ganglionic bodies are at present practically unknown.

(e) Lesions (tumors, etc.) of the lobi optici (tubercula quadrigemina) are productive of early neuro-retinitis and blindness, of convulsions, and of diffused bilateral incomplete paralysis of the body, without symptoms

of disease at the base of the brain (*vide infra*). The diagnosis *intra vitam* remains of great uncertainty, inasmuch as other lesions in the median line, involving parts adjacent to the lobi optici, may give rise to the same symptom-group.

2. FOCAL LESIONS OF THE CEREBELLUM.—(a) Lesions strictly limited to one lateral lobe or hemisphere of this organ do not give rise to

FIG. 10.

FIG. 11.

any characteristic symptoms—in some cases, indeed, to no symptoms at all. When the lesion tends basad, irritating and compressing the subjacent pons and oblongata on one side, incomplete paralysis appears in the limbs opposite the lesion, the face usually remaining normal. Occipital

headache, attacks of vomiting, opisthotonos, or intense subjective stiffness of the back of the neck, with neuro-retinitis, would strengthen the diagnosis. If the lesion extend laterad, so as to involve the processus ad pontem (lateral peduncle), a tendency to rotate while lying or to deviate in walking toward the side of the lesion may be added.

(b) Lesions of the middle lobe, or vermis superior in particular, may be positively recognized during life. Besides the above-mentioned general symptoms of cerebellar and bulbar irritation and compression—viz. occipital headache, cervical stiffness, attacks of vomiting, neuro-retinitis, and atrophy of the optic nerve—there is a very characteristic, almost pathognomonic, symptom. This is cerebellar titubation, miscalled cerebellar ataxia. The patient, whose equilibrium may be perfect while lying or sitting, upon rising and attempting to walk does so somewhat like an intoxicated person: the head and body are bent forward; the arms and hands held out and moved as balancing weights; the feet are widely separated, the toes clutching the floor or carpet; the body oscillating somewhat over its base of support. There are not the wide excursions of the entire body, the zigzagging, of alcoholic intoxication, nor is there any of the stamping or jerky step of locomotor ataxia. If the patient be tested lying or sitting, it is found that neither in the hands nor in the legs is there a trace of ataxia: muscular strength and sensibility are long preserved, and the patellar reflex is exaggerated.

3. FOCAL LESIONS OF THE BASE OF THE BRAIN, either within the nervous substance or springing from the dura, and acting by irritation and pressure upon various parts of the basal aspect of the encephalic mass.

(a) Diffused bilateral lesions of this class situated frontad of the crura give rise to more or less distinct symptoms, and a diagnosis is sometimes possible. (1) Lesions in the vicinity of the sella turcica and optic chiasm produce symptoms in the optic apparatus very early, and these remain prominent throughout the illness. These symptoms are, irregular (at least not lateral) hemianopsia, neuro-retinitis followed by atrophy of the optic nerve, temporary or permanent paralysis of one or several ocular nerves. If these exist without symptoms of lesion of other parts of the brain (reasoning by the process of exclusion), we may strongly suspect the seat of the lesion to be in the region named. Other symptoms are paroxysmal headache and occasional vomiting, epileptiform convulsions (never Jacksonian in distribution), partial hemiplegia, or general muscular weakness. By such data we were recently led to the correct localization of a tumor. (2) If the lesion be farther frontad—*i. e.* strictly in the orbital areas of the basis cerebri—anopsia, uni- or bilateral, usually with hallucinations of smell, will be an early symptom, along with neuro-retinitis and obscure motor and sensory symptoms (headache and convulsions more especially).

(b) Lesions situated caudad of the infundibulum. (1) Bilateral lesions give rise to symptoms which are the symmetrical duplication on either side of the face and body of those to be next described as characteristic of—

(2) Unilateral focal lesions of the base of the encephalon from the crura caudad to the pyramidal decussation.

In a general way, the symptoms of these lesions are designated as varieties of crossed paralysis.

Clinically, a crossed paralysis is one in which one or several cranial

nerves show symptoms of irritation or destruction on one side of the median line, while body symptoms are present on the opposite side.

Physiologically and anatomically, a crossed paralysis is one in which the lesion is so placed as to affect a cranial nerve (or more than one) at a point caudad (below) of the decussation of the fibres which connect its nucleus with the cerebral cortex, or at its nucleus of origin, or so as to injure the nerve-trunk itself; while at the same time the lesion affects the main fasciculus of the pyramidal tract frontad (above) of its decussation, in the crus, pons, or oblongata.

In many cases of crossed paralysis, besides common motor and sensory symptoms, there is apt to be neuro-retinitis with its consequences.

The chief forms or types of crossed paralysis are :

(*α*) Lesions involving the meso-ventral aspect of one crus cerebri. The direct symptoms of such a lesion are in the range of distribution of the motor oculi (N. iii.), such as ptosis, mydriasis, external strabismus, and heteronymous diplopia; the crossed symptoms are more or less complete paralysis of the lower part of the face and of the extremities on the opposite side (hemiplegia). This relatively frequent form of crossed paralysis we designate as the eye-and-body type.

(*β*) The lesion occupies the latero-ventral part of the crus. This rare localization would give rise to direct paralysis of the fourth nerve, indicated by homonymous diplopia in the lower inner field of vision; to lateral hemianopsia with dark half-fields opposite the lesion, from injury to the tractus opticus (vide Fig. 8); and to a mixed motor and sensory disturbance in the opposite side of the face and body, without anæsthesia of the olfactory and auditory apparatus. A very large lesion involving almost the entire crus would probably also cause direct paralysis of N. iii.

(*γ*) Lesion of the basal part of the pons frontad of an imaginary transverse line passing through the apparent origin of the trigemini (NN. v.). Symptoms: A common hemiplegia of the lower face and extremities on the opposite side with neuro-retinitis and other general signs of basal disease. The abducens nerve (N. vi.) would in some cases be involved in its course frontad over the pons, giving rise to internal strabismus and homonymous diplopia on the same side as the lesion.

(*δ*) A focal lesion in the caudo-ventral part of the pons—*i. e.* caudad of an imaginary transverse line passing through the trigemini roots—gives rise to highly characteristic symptoms. These are: Direct paralysis of the face, not (?) affecting all the muscles, but without De R., and common hemiplegia of the limbs on the opposite side.

If the lesion be strictly basal—*i. e.* one springing from the membranes or bone, the trunks of the sixth and seventh (facial) nerves are directly injured, and the resulting facial paralysis is of the peripheral form, affecting all the muscles and yielding De R. The body symptoms on the side opposite the lesion are less marked.

In the first category of cases, those in which the lesion is in the substance of the pons, the motor fasciculus from the cortex cerebri to the nucleus of N. vii. is injured caudad of (below) its theoretical decussation-point on the middle part of the pons, while the pyramidal tract is involved frontad of (above) its decussation.

This symptom-group is known as face-and-body type, or as crossed hemiplegia, strictly speaking.

(ε) A lesion so placed laterally in or on the pons as to affect the origin of one trigeminus (N. v.) will cause, besides motor symptoms in the face and body (types α or δ), special direct symptoms—viz. anæsthesia in the distribution of the fifth nerve and paralysis of the masticatory muscles opposite to the body symptoms. This is the trigeminus and body type.

Lesions may be so placed ventrad or laterad upon or in the oblongata as to give rise to other types of crossed paralysis: these are easily assumed in a theoretical manner, but in practice such cases are extremely rare, present a complicated semeiology, and are usually not correctly diagnosed during the patient's life.

V. Cranio-cerebral Topography.

The study of cerebral localizations from a diagnostic and practical point of view would be incomplete without a brief reference to the relations existing between the various gyri of the cerebrum and the external surface of the head, in order to render more accurate the estimation of the actual location of cerebral injuries and diseases.

The surgical anatomy of the head with reference to its contents has been developed with remarkable completeness during the past fifteen years, chiefly by the researches of Broca, Bischoff, Heftler, Turner, and Féré. Acting upon these data, a number of surgeons have successfully trephined the skull for the result of injuries, for abscess, and even for tumors.

The location of many convolutions and fissures of the cerebrum can be accurately mapped out upon the surface of the skull, or even upon the head of the living subject, from the projections of certain lines and measurements from points thus obtained, as well as from some natural landmarks. For the projection of these lines the head is placed in a particular position, as can easily be done when we operate upon a bare skull, but which can also be approximated when we deal with a living subject either sitting or lying in bed. The skull or the shaven head should be so placed and held that a line passing from the alveolar process of the superior maxilla and through the lowest part (condyles) of the occipital bone shall be truly horizontal. The greatest care should be used to determine this line—the alveolo-condyloid plane of Broca—for upon it all other projections and measurements are based. This position of the head and the alveolo-condyloid plane (line 1-1) are represented in Fig. 12, p. 94.

From this line (1-1) a vertical line, or one exactly perpendicular to the first, is drawn through the external auditory meatus. At the top of head this line—the auriculo-bregmatic line ($\Lambda \Lambda$)—indicates the bregma or true vertex, which important landmark is to be marked with carmine or aniline upon the scalp. Upon the top of the head an imaginary horizontal line (4-4), parallel with the alveolo-condyloid plane, is projected, and upon it we measure backward a distance of 50 mm. (2 inches), and then draw a second vertical line ($B B$). At the point where this line reaches the convexity of the head is the Rolandic point (R), under which,

in average heads, lie the upper or posterior extremity of the fissure of Rolando, the upper ends of the pre- and postcentral gyri, and within the longitudinal fissure the paracentral lobe, which together constitute the cortical centre for the leg of the opposite side. The Rolandic point, thus determined, should be distinctly marked upon the shaven scalp.

A third horizontal line is next to be drawn from the external angular process of the frontal bone backward, parallel with Broca's plane. This

FIG. 12.

Topographical Lines applied to the External Contour of the Head.

line (2-2), which may be termed the fronto-lambdoid because its posterior extremity usually passes at or near the upper angle of the lambdoidal suture, serves for the determination of several important parts. In the first place, the line (2-2) passes at about 5 mm. above the upper border of the squamous suture, or through it, and under this line, mostly

parallel to it, are the anterior two-thirds of the fissure of Sylvius. Secondly, at about 5 mm. above and behind the intersection of lines (A A) and (2-2) is the inferior extremity of the fissure of Rolando, bounded by the pre- and postcentral gyri. In the third place, upon this line (2-2), at a distance of 18 or 25 mm. behind the external angular process, is the folded part of the base of the third frontal gyrus or Broca's speech-centre (F 3).

FIG. 13.

Topographical Lines applied to Henle's Figure of the Skull. Location of the Rolandic point. Rolandic line, motor-centres, and the branches of the middle meningeal artery.

Having exactly determined and marked the situation of the Rolandic point and of the inferior termination of the fissure of Rolando above the ear, these two points are to be connected by a line, which is represented on the diagram by a black bar. This, the Rolandic line, is the guide for nearly all operations for the relief of spasm or paralysis of traumatic origin, or of such as may be caused by tumors, abscesses, etc. It is surrounded by the so-called motor centres for the face, arm, and leg (?) as demonstrated by experiments upon animals and by now numerous autopsies in human cases of injury and disease.

Other relations of interest are the apex of the temporal lobe, a little beneath the line (2-2) and at about 10 to 15 mm. posterior to the external angular process of the frontal bone; the situation of the occipito-parietal fissure, almost immediately under the posterior end of the line (2-2) at its junction with the lines (E E), which indicate the posterior extremity of the cerebrum; the anterior end of the brain being marked off by the line (D D).

Furthermore, for certain purposes the limits of the basal or central ganglia may be estimated as follows: Their superior limit is indicated by a horizontal line (3-3) drawn at 45 mm. below the vertex, their anterior limit corresponding to the head of the nucleus caudatus by the vertical line (C C), and their posterior limit, the hinder end of the thalamus, by the vertical line (B B).

Upon the median line at the top of the head an allowance of full 15 mm. should be made for the width of the superior longitudinal sinus separating the hemisphere.

FIG. 14.

The same Topographical Lines applied to the Left Cerebral Hemisphere in Henle's Skull. The motor centres are approximately indicated by dotted lines. (The leg centre should be reduced in size as it lies near to and in the longitudinal fissure.) The Rolandic line is placed a little behind the fissure for the sake of clearness.

The location of the middle meningeal artery, which so often furnishes the blood that compresses the brain after various injuries to the head, is surgically of great importance. The course of its two principal branches is approximately indicated upon Fig. 13 by the branching lines drawn on the anterior inferior angle of the parietal and the upper part of the squamous portion of the temporal bone. In the living subject the main trunk of the artery would be found under the horizontal line (2-2) a little posterior to the speech-centre, about 30 mm. behind the external angular process, and in front of the beginning of the fissure of Sylvius.

Upon the shaven head of a patient seated in a chair or lying in bed the principal landmarks and relations above defined can be mapped out with sufficient approximation to accuracy by the use of a ruler to mark

the alveolo-condyloid plane, and a cardboard cut so as to stand astride the head in the auriculo-bregmatic vertical. A light wooden apparatus can easily be made to indicate these two lines, while the remaining measurements can be made with a steel tape-measure, and the points marked with carmine ink or an aniline pencil.

The value of cranio-cerebral topography is obvious for ordinary surgical purposes, but it may in the future prove of great utility in the treatment of cerebral diseases (tumors, abscesses, etc.) by surgical means. A bold and nearly successful attempt at removing a tumor of the brain has already been made,¹ and doubtless there are surgeons who will not hesitate to follow the path thus opened up when physicians give them a diagnosis of localized tumor or abscess in parts of the cortex cerebri to serve as a basis.

The indications for trephining or raising bone after cranial injuries, for the relief of symptoms of cerebral irritation, compression, or disorganization, may be provisionally stated as follows:

(a) When aphasia supervenes immediately or within a few days or weeks after an injury of the anterior portion of the head on the left side. It is extremely probable that in the first case a clot or bony spiculum will be found compressing the speech-centre; in the second case, that an abscess has formed in or near it (Broca's case).

(b) When simple hemiplegia or hemiplegia with hemispasm follows an injury, however slight, in the temporo-parietal region. If the paralysis or spasm be limited to one side of the face or to one extremity, the indication to operate is even stronger. Even if in such cases the injury be not immediately over the motor area, the surgeon is justified in exploring that region.

(c) In conditions of stupor and coma after cranial injuries, sometimes without external wound, in which meningeal hemorrhage is the cause of impending death, the discovery of slight hemiplegia should justify trephining planned according to the topographic rules above laid down (Weir's case, 1882). In some cases latent hemiplegia may be discovered by the presence of an erythematous flush on one buttock and of a slightly increased peripheral temperature (taken between fingers or toes).

(d) In the very rare cases in which paralytic phenomena are found on the same side as the evident cranial injury, it would be proper to trephine on the opposite side of the skull in search of fracture or hemorrhage, the result of contre-coup.

(e) In chronic epilepsy after traumatism of the head the indication for trephining is present, but it is seldom a specific indication connected with the subject of localization. Lesions of any part of the skull and dura may be a cause of epileptic attacks, irrespective of motor centres.

(f) In cases of tumor in the motor centres, if there be not symptoms of tumors in other parts of the brain (multiple tumors) or of penetration of the tumor to the central parts of the brain, we believe trephining not only justified, but demanded in the present state of science.

Some of the contraindications to trephining may be thus stated:

(a) Whenever in apparently favorable cases there are signs of injury to the base of the brain, such as paralysis of cranial nerves, neuro-retini-

¹ Bennett and Godlee, *The Lancet*, 1884, ii. 1090; 1885, i. p. 891.

tis, and Cheyne-Stokes respiration (although the last symptom may occur from simple compression).

(b) When hemispasm or hemiplegia is accompanied by hemianæsthesia, thus making it probable that the lesion is deeper and farther back.

It should be added, in conclusion, that these indications and contra-indications are formulated from the standpoint of the neurologist.

MENTAL DISEASES.

By CHARLES F. FOLSOM, M. D.

DEFINITIONS OF INSANITY.—The term insanity conveys quite different meanings to the community, to lawyers, and to physicians. From the three points of view its definition has been constantly widening for the past century. A great part of the alleged recent increase in insanity is due to the fact that its definition is applied to more people. Our insane asylums are more quiet and orderly, not only because of the more humane treatment of the inmates, but largely also because quieter and less insane people are now sent there than formerly. Doubtless the mistake is sometimes made of going so far, in zeal for science and philanthropy, as to make the definition of insanity too broad; and in a refined civilization the nice adjustment of complicated social relations, or even a fastidious taste, requires people to be sent to insane asylums who in simpler states of society would be cared for at home.¹

The popular idea of insanity is of wild, incoherent, or crazy conduct. If maniacal, the timid or frightened young girl who would not hurt a fly, and the tottering, harmless old man if confused and partly demented, are hurried off to the asylum with the use and show of force suitable for a desperate criminal, while the victim of overwhelming delusions, because he seems clear, logical, and collected, is vigorously defended against the physician's imputation of insanity until he commits an offence against the laws, when he is fortunate if he is not treated as a criminal. It is often impossible for judges, juries, counsel, and even medical experts, to wholly divest themselves of the popular notions of insanity in cases appealing strongly to the passion or prejudice of the day. Cases involving the question of responsibility for crime are decided against science and the evidence because of certain preconceived notions upon insanity which no amount of skilled opinion can controvert. Jurors, and less often judges, make up their minds what a sane man would do under given conditions, and of what an insane man is capable, judging from the facts within their own experience; and in forming their decisions it is the act itself, and not the man, diseased or otherwise, in connection with the act, that chiefly governs them. Often they are right, not seldom wrong. Strange, apparently purposeless, illogical, inconsistent action is frequently attributed to the author of it being insane on that subject, whereas he may be sim-

¹ The physician in general practice is referred to Clouston's *Clinical Lectures on Mental Diseases*, and to Part I of Spitzka's *Manual of Insanity*. For those who wish to study insanity thoroughly the literature is rich and its bibliography is readily available. Of many parts of the subject only an outline, of course, can be given within the limits of the present paper.

ply acting from strong impulse or emotion, and may be by no means insane. On the other hand, because a man knows right from wrong in the abstract, and can ordinarily behave well, the very characteristic workings of his insane mind are often seized upon as unquestionable proof of sanity, even when they admit of no other explanation to the skilled physician than that of insanity. There is no doubt of the fact that the whipping commonly used in the treatment of the insane by the monks several centuries ago put an end to much insane conduct; and in insane asylums now, in spite of the best efforts of the medical staff to the contrary, a brutal, bullying patient is sometimes struck by another patient or an attendant in return for some unusually exasperating and cruel conduct, with the result of making him behave well in the future. It is with reference to this class of cases that the crowd oftenest errs in its definition of insanity. Society claims a voice in the enforcement of the laws for its own protection, assuming to know who could control themselves from crime and who not, and naturally wishes the standard of responsibility to be kept high. Of course its sympathies and prejudices largely govern its voice in the matter.

With precisely the same degree of insanity and the same power to control their actions two murderers may be sentenced, one to death for an act where the motive and method were those of the criminal, and the other to an insane asylum for killing a person under circumstances which are not explainable by sane reasons. The Pocasset Adventist who sacrificed his loved child, as he thought, by the Lord's command, would probably have been hanged if he had committed a crime similar to John Brown's, Wilkes Booth's, Orsini's, or Guiteau's. Sometimes the accused gets the benefit of the doubt, and sometimes society, according to the view of the merits of the case taken by the judge in his charge or by the jury in their verdict.

To the lawyer insanity means only a condition of mind with reference to certain conduct. An insane man is simply *non compos mentis*. Insanity is irresponsibility. The whole question to the lawyer is with regard to a certain act or series of acts. The lawyer's definition is narrower than that of the physician. In wills and contracts the course is usually clearer than when there is a question of serious crime, and even an insane person in an asylum may be a party to a valid contract or make a will that will hold in law. It is not necessary that a will or contract be such as would be made by a just man or a reasonable man, but simply that it fairly represent the wishes and character of the man making it, uninfluenced by any insane delusion or prejudice caused by mental impairment; that the will or contract in itself bear evidence of a correct appreciation of the circumstances and conditions of the case; and that the mind be able to act independently enough, with a reasonable knowledge of the duties of the individual and the just rights of others. An unsound mind, as defined by the physician, would cover a large portion of the convicts in our workhouses and prisons to-day if they could be critically examined, but the lawyers and courts would not find many of them insane. A man is not insane in law unless his act is traceable to, or its nature has been determined by, mental disease affecting his free agency; in other words, unless insanity caused his act either wholly or in great part.

In the partly irresponsible condition of mind often produced by grave hysteria, so-called nervous prostration, and the general mental and moral demoralization often seen in seduced and abandoned women, or after exhausting illness, or following apparent recovery from cerebral hemorrhages or embolism, blows upon the head, sunstroke, chronic alcoholism, syphilis, etc., there may be loss of self-control and a distinct moral perversion or decided change of character without very evident mental impairment; and the courts recognize a diminished capacity, as the result of disease, to appreciate and follow what is right and just and to avoid what is wrong or unjust, and yet not complete irresponsibility. In this connection the fact should be borne in mind that a very little mental disease can make bad people criminals, and may not take others beyond the bounds of propriety. A criminal may become insane and be still pretty much the same kind of a criminal as before. Morality, too, is relative, and many criminals, like children, know almost nothing of abstract truth, justice, or virtue, because they have never been taught them; and there are many cases where the perverse or criminal actions of people may be about equally explainable on the theory of insanity or wickedness. The criminal, a creature of his surroundings and associations, may often not be discriminated from the man with mental disease. Indeed, it is not difficult to take the philanthropic position that all criminals are insane because they are not in sympathy with the moral conceptions of their time, or, to use the fashionable expression of the day, because they are not in harmony with their environment. Such a view of crime, however, leads to only one of two conclusions—either that insanity is no sufficient defence for wilful violation of the laws, or that all criminals should be treated as persons of unsound mind.

The free agency of the individual is affected or modified in many different ways by the different diseases of the mind, and the question of responsibility will often be found to be one of the most perplexing problems with which the physician has to deal. If well-marked forms of insanity alone were to be investigated, the matter would be comparatively a simple one; but such is far from always being the case. The insane man often commits certain crimes precisely as an ordinary sane criminal would do the same thing. Often the evidence is contradictory, the testimony as to previous life and character conflicting, and the disease of so obscure a stage or type that it is almost impossible to form a clear opinion. The determination of a man's degree of free agency is no simple affair which can be decided in all cases by a few or a few dozen interviews. Not seldom the mystery remains unsolved after the autopsy. Man's free will is not the property of any substance which can be demonstrated by chemistry, physiology, or microscopical research, but it is the result of the combined action of a whole group of functional activities the very relations of which to each other are as unknown as their method of action. No stethoscope or ophthalmoscope can reveal its morbid action, which can only be inferred indirectly from the operations of the mind.

The cases in which the physician is called upon to define insanity as the term is used by the lawyers are (1) to secure limitation or control of an individual's actions, usually by a guardianship; (2) to control him absolutely in an asylum; (3) to estimate his culpability or criminality, or

his capacity to make a will or contract or to transact business. It is quite important, therefore, that the medical man should understand that there may be, as regards some particular person, a wide difference between medical insanity or mental disease and legal insanity or irresponsibility. He does most wisely when he confines his testimony to an explanation of the changes caused by disease in the particular case, and to the effect of such changes upon the mind, leaving to the judge's charge and the jury's verdict the questions of guilt and responsibility.

Insanity may be of congenital origin or slowly developed from early childhood, but usually it indicates a change caused by disease, so that the person alleged to be insane must, as a rule, be compared with himself at some previous time, and not with some ideal standard of mental health which does not exist. Indeed, if we could measure nicely no two of us could be fairly held to precisely the same degree of accountability. The knowledge of right and wrong is not a fair criterion, as many insane men possess that knowledge well enough in the abstract. The ability to distinguish right from wrong in the particular act is possessed by some insane persons whose will and power of self-control have become so limited by disease that they cannot avoid what they know to be crime. Delusion overpowering the mind is sufficient evidence of irresponsibility, but all delusions are by no means so powerful that they cannot be resisted, and many must be classed as simply false beliefs or mistaken views which could be, and should be, controlled. In case, therefore, of alleged delusions not manifestly insane further evidence of insanity is required, and the way in which a man believes or does anything may be more of an indication as to the soundness or unsoundness of his mind than what he believes or does. A crime committed under the influence of maniacal delirium, acute delirious mania, epileptic furor, uncontrollable impulse, alcoholic insanity, or hysterical mental disease will usually explain itself, while a demented insane person is so characteristic an object that his crime cannot well be mistaken for that of a responsible agent.

The different conditions of mind grouped under the general terms moral insanity, affective insanity, and impulsive insanity are still the bugbear of jurists, and there is a wide difference of opinion as to the degree of accountability for actions performed under the influence of moral perversion with only slight intellectual impairment; but the degree to which the individual deviates from the path of the law may depend more upon his training and surroundings than upon his disease—points which must always be considered in establishing a definition of insanity in obscure cases. Of two persons whose circumstances in life, in connection with a certain amount of disease, have produced as nearly as possible identical morbid mental states, it now and then happens that the necessary surroundings of the one steady and support him, while the associations and conditions of life throw the other still more off his balance. The one is able to sustain the ordinary relations with the world, the other not.

The intelligent study of mental disease by medical men has resulted in its being detected at so early a stage and in such a mild form that its proper treatment might almost be called, when successful, the prevention of insanity. Cerebro-mental disease, though it be only in its incipient form, implies to the physician the necessity for medical treatment; but it

is another question whether the disease is sufficient in amount to impair the power of self-control and will so as to determine irresponsibility. It is not the doctor's province to punish for crime, but to treat for disease, and he often forgets that fact. The various medical definitions of insanity in textbooks and on the witness-stand do not clearly enough state how far the medical and how far the forensic meaning of the word is implied. What seem to be wide differences of opinion regarding responsibility for crime, as given in the courts, are often due to different ways of stating the question, and nothing more.

Boileau said that all men are insane, the only difference between them being the varying degrees of skill with which they are able to conceal the crack; and Montesquieu, that insane asylums are built in order that the outside world may believe itself sane. In 1832, Haslam, one of the first experts in mental disease in England at that time, testified in court that he had never seen a sane man in his whole life, adding, "I presume the Deity is of sound mind, and He alone."

It is impossible to give a satisfactory definition of insanity, to draw any hard and fast line on one side of which we should put all the sane, and on the other all the insane. It is not possible to divide insanity from sanity by a single criterion, such as the existence of delusions, inasmuch as many sane people have very curious delusions; for instance, Sir William Blackstone's belief in witchcraft, as stated in his *Commentaries on the Laws of England*; Martin Luther's assertion that he saw the devil and threw an inkstand at him at a time when a belief in a personal devil was required by the canons of the Church of England; Napoleon's faith in his star; the common belief of the French generals that Joan of Arc's hallucinations were divine messages. Insane delusions have been defined as false beliefs, impossible from the nature of things or the circumstances of the case, according to general belief. One can only judge of each case and each person by the conditions attending them. A belief consistent with one person's whole life and character might indicate such a change in another as to be a mark of insanity.

Hallucinations—"psycho-sensorial disturbances characterized by sensations perceived when the exercise of the sense has not been determined by any external excitation"—are characteristic of many conditions of disturbed health besides insanity; and the same is true of illusions—erroneous interpretations of sensations actually perceived. In both cases the existence of insanity is determined by the fact whether or not the erroneous impressions are corrected by the judgment. An important point is to consider most carefully every unnatural, strange, or unexplained action, whether deliberate or from impulse, particularly in the large class of eccentric, ill-balanced, or weak-minded persons on the border-line between sanity and insanity. There are people who at one time seem to belong to the sane and at another to the insane class. Bail-larger states that the essential element of insanity is loss of free will. Ball of Paris describes an insane man as one who, in consequence of a profound disturbance of the intellectual faculties, has lost more or less completely his free will (*liberté morale*), and has ceased thereby to be responsible to society for his actions.

Bucknill describes insanity, in his Sugden prize essay, as "a condition of the mind in which a false action of conception or judgment, a defec-

tive power of the will, or an uncontrollable violence of the emotions and instincts has been separately or conjointly produced by disease." Maudsley's definition is, "Insanity is, in fact, disorder of brain producing disorder of mind; or, to define its nature in greater detail, it is a disorder of the supreme nerve-centres of the brain—the special organs of mind—producing derangement of thought, feeling, and action, together or separately, of such degree or kind as to incapacitate the individual for the relations of life Mind may be defined physiologically as a general term denoting the sum-total of those functions of the brain which are known as thought, feeling, and will. By disorder of the mind is meant disorder of those functions."

Bucknill considers insanity a disease of the brain affecting the integrity of the mind. Maudsley calls it a disorder of the mind of such a degree as to incapacitate one for the ordinary relations of life, implying that there may be certain deviations from the condition of sound mind which do not constitute insanity. Tuke's definition is that "insanity consists in morbid conditions of the brain, the result of defective formation or altered nutrition of its substance, induced by local or general morbid processes, and characterized especially by non-development, obliteration, impairment, or perversion of one or more of its psychical functions." Instead of itself being a disease, insanity, properly speaking, is a symptom of diseases which under varying manifestations probably affect different functions of the brain—at least they affect the brain in different ways.

As Krafft-Ebing says, "It is a logical, self-evident proposition that the organ whose function under normal conditions is to bring about all mental processes must be the seat of changes when these functions are disturbed;" and Schüle adds, "The study of disturbances of the mind involves the changes of the normal mental functions produced by disease. . . . Mental diseases are brain diseases, but they are more than that." The normal action of the mind is a strange combination of reason and impulse, varying greatly in different persons, and in the same person at different times and under varying influences. The relations of the one to the other, and their influence on action, often change, under varying conditions and circumstances, in sane persons, but still more in the insane.

Lord Bramwell once said that insanity is strong but not conclusive evidence of innocence; and Lord Blackburn has stated that the jury must decide in each individual case whether the disease of the mind or the criminal will was the cause of the crime. The position of Sir James Stephen in his *History of the Criminal Law in England* best states the most recent views of irresponsibility—namely, that "no act is a crime if the person who does it is, at the time when it is done, prevented either by defective mental power or by any disease affecting his mind from controlling his own conduct, unless the loss of the power of control has been produced by his own default." He says that a man laboring under such a defect of reason that he does not know that he is doing what is wrong may be defined as one deprived, by disease affecting the mind, of the power of passing a rational judgment on the moral character of the act which he meant to do. There are persons too insane to make a valid will by virtue of a single delusion, whose right to vote, under the law prohibiting the insane from voting, would not be questioned. Another

might not be held responsible for crime, and still make a contract involving the rights of others besides himself that would hold in law.

Bucknill's recent medico-legal definition of insanity is, incapacitating weakness or derangement of mind produced by disease; meaning, in criminal cases, inability of abstaining from the criminal act, which would be expressed by Lord Bramwell's test, Could he help it? Bucknill suggests as an amendment to the law of England that no act is a crime if the person who does it is at the time incapable of not doing it by reason of idiocy or of disease affecting the mind.

Any definition of insanity would be incomplete without the statement of Hughlings Jackson's view, that disease only produces negative mental symptoms answering to dissolution, and that all elaborate positive mental symptoms (illusions, hallucinations, delusions, and extravagant conduct) are the outcome of activity of nervous elements untouched by any pathological process; that they arise during activity on the lower level of evolution remaining; that the insane man's illusions, etc. are not caused by disease, but that they are the outcome of activity of what is left of him (of what disease has spared), of all there then is of him. His illusions, etc. are his mind.

THE CLASSIFICATION OF MENTAL DISEASES.—There is no universally accepted classification of mental diseases, and the same terms even are used by different writers to convey entirely different meanings. The classification according to the causes of insanity was suggested by Morel of Paris, and fully elaborated by Skae of Edinburgh, as follows: (1) Moral idiocy; (2) intellectual idiocy; (3) moral imbecility; (4) intellectual imbecility; (5) epileptic insanity; (6) insanity of masturbation; (7) insanity of pubescence; (8) hysterical mania; (9) amenorrhœal mania; (10) post-connubial mania; (11) puerperal mania; (12) mania of pregnancy; (13) mania of lactation; (14) climacteric mania; (15) ovario- and uteromania; (16) senile mania; (17) phthisical mania; (18) metastatic mania; (19) traumatic mania; (20) syphilitic mania; (21) delirium tremens; (22) dipsomania; (23) mania of alcoholism; (24) post-febrile mania; (25) mania of oxaluria and phosphaturia; (26) general paralysis; (27) epidemic mania; (28) idiopathic sthenic mania; (29) idiopathic asthenic mania.

In a large proportion of cases the causes of insanity are so many and so complex that it is not within human power to say which of a number has been the most important, or the assigned and classified cause may be only an accidental complication or the most striking, but by no means most potent, cause.

The classification, according to the functions interfered with, is that adopted by Maudsley and by Bucknill. According to Bucknill, we have

(1) Insanity of the intellect or ideas: Idiocy, imbecility, dementia, delusional insanity, monomania, mania.

(2) Insanity of the feelings and the moral sentiments: Moral imbecility, moral insanity, melancholia, religious insanity, hypochondriacal insanity, nostalgic hypochondriacal insanity, exaltation regarding religion, pride, vanity, ambition.

(3) Insanity of the propensities, instincts, or desires: Mania, homicidal mania, suicidal mania, erotomania, dipsomania.

Maudsley's classification, according to the faculties thought to be affected,

is also inconsistent: I. Affective insanity: (1) Simple mania; (2) simple melancholia; (3) moral insanity. II. Ideational insanity: (1) General (acute and chronic mania and melancholia); (2) partial (monomania and melancholia); (3) dementia (primary and secondary); (4) general paralysis; (5) idiocy and imbecility.

The classification according to symptoms is most generally adopted, being used, more or less modified, in Germany, generally in France, and more commonly than any other in this country and in England. It has been suggested by different writers in a dozen different forms, differing only in details. Griesinger's is as follows:

(1) States of mental depression: Hypochondriasis; simple melancholia; melancholia with stupor; melancholia with destructive tendencies; melancholia with persistent excitement of the will or impulse (moral insanity).

(2) States of mental exaltation: Mania; monomania.

(3) States of mental weakness: Chronic mania; dementia; idiocy; cretinism.

As important complications of insanity he places general paralysis of the insane and epilepsy, and various disorders of sensation and movement, such as convulsive gait, general cramps, choreic movements, hyperæsthesia of the skin, etc.

A classification according to the morbid condition of the brain has thus far proved unsuccessful. Up to the present time this remains largely a field of speculation, and even with the immense progress of the past dozen years it is a subject upon which there is now little definite to be said. Voisin's system is purely visionary—namely: I. Idiopathic insanity, due to vascular spasm. II. Insanity dependent on brain lesions: Congestive insanity; insanity from anæmia; atheromatous insanity; insanity from brain tumors. III. Insanity from alterations of the blood: Diathetic insanities; syphilitic insanity.

In basing his nomenclature on the clinical history of the various forms of insanity, Clouston makes his classification as follows:

(1) States of mental depression (melancholia, psychalgia): (a) Simple melancholia; (b) hypochondriacal melancholia; (c) delusional melancholia; (d) excited melancholia; (e) suicidal and homicidal melancholia.

(2) States of mental exaltation (mania, psychlampsia): (a) Simple mania (*folie raisonnante*); (b) acute mania; (c) delusional mania; (d) chronic mania.

(3) States of regularly alternating depression and exaltation (*folie circulaire*, psychorhythm, *folie à double forme*, circular insanity, periodic mania, recurrent mania).

(4) States of fixed and limited delusion (monomania, monopsychosis): (a) Monomania of pride and grandeur; (b) monomania of unseen agency; (c) monomania of suspicion.

(5) States of mental enfeeblement (dementia, amentia, psychoparesis, congenital imbecility, idiocy): (a) Secondary (ordinary) dementia (following acute or subacute disease, ending in chronicity); (b) primary enfeeblement (imbecility, idiocy, cretinism), the result of deficient brain development or of brain disease in very early life; (c) senile dementia; (d) organic dementia (the result of organic brain disease).

(6) States of mental stupor (stupor, psychocoma): (a) Melancholic

stupor (*melancholia attonita*); (*b*) anergic stupor (primary dementia, *dementia attonita*); (*c*) secondary stupor (transitory, after acute mania).

(7) States of defective inhibition (*psychokinesia*, *hyperkinesia*, impulsive insanity, volitional insanity, uncontrollable impulse, insanity without delusion): (*a*) Homicidal impulse; (*b*) suicidal impulse; (*c*) epileptiform impulse; (*d*) animal impulse; (*e*) dipsomania; (*f*) pyromania; (*g*) kleptomania; (*h*) moral insanity.

(8) The insane diathesis (*psychoneurosis*, *neurosis insana*, *neurosis spasmodica*).

Some of the German mental pathologists have endeavored to combine in their classification the clinical history with the little that is known of its morbid anatomy. Meynert has gone so far in this direction as to have constructed an ideal mental pathology belonging to the sphere of brilliant speculation rather than exact science. Schüle has well summarized our knowledge on these points, as follows:

I. States of mental defect or degeneration. (1) States of mental defect: (*a*) Microcephalism; (*b*) idiocy. (2) States of mental degeneracy, chiefly as the result or further development of (*a*) Hereditary insanity, impulsive insanity, moral insanity; (*b*) insanity from the severe neuroses, epileptic insanity, hysterical insanity, hypochondriacal insanity; (*c*) periodic and circular insanity.

II. Insanity in persons of full mental and physical development:

(A) The cerebral neuroses causing mental disease, affecting primarily the mind alone (*psychoneuroses*): (1) The acute or subacute typical cerebral neuroses in healthy neurotic persons and with a vaso-motor origin: (*a*) Primary form, *melancholia*, *melancholia agitata*, simple mania; (*b*) secondary form, chronic mania and monomania, dementia. (2) The chronic cerebral neuroses giving rise to mental disease founded on degeneration and of neurotic origin primarily (*delusional insanity*): (*a*) Primary monomania of persecution, with a condition of pure mental depression or with exaggerated and exalted ideas; (*b*) delusional insanity, strictly speaking, psycho-convulsive form (*maladie du doute*), psycho-cataleptic form (*delusional insanity* attended with anomalies of sensation).

(B) The organic mental diseases affecting the psychic functions (*cerebro-psychoses*), differing from (A) chiefly in being deeper-seated: (1) With motor symptoms of excitement (acute mania): (*a*) *Mania furiosa* (including *mania transitoria*); (*b*) *mania gravis*; (*c*) acute delirious mania. (2) With motor neuroses and symptoms resembling catalepsy, tetanus, and anergic stupor, or the various forms of *Spannungsneurosen*: (*a*) *Melancholia attonita*; (*b*) delusional stupor; (*c*) primary dementia (stupor), acute and chronic. (3) With progressive paralysis, the typical form of paralytic dementia.

(C) The distinct lesions of the brain, giving rise secondarily to psychological disturbances. The modified paralyses or cerebral diseases in which dementia and paralysis are both observed clinically: (*a*) Meningo-peri-encephalitis, chronic and subacute; (*b*) pachymeningitis and hæmatoma; (*c*) diffuse encephalitis with sclerosis, without mental excitement and with mental excitement; (*d*) diffuse encephalitis with local softening, apoplexy, capillary aneurisms in groups or singly, multiple sclerosis; (*e*) diffuse encephalitis arising from foreign growths in the brain; (*f*) chronic peri-

encephalitis, with previous *tabes dorsalis*; *tabic* paralysis; (*g*) primary atrophy of the brain, with accompanying spinal *tabes*, *tabic* dementia; (*h*) syphilitic encephalitis, with disturbances of the mind.

Krafft-Ebing's classification is as follows:

A. Mental Diseases of the Normal Brain.—I. Psychoneuroses: 1. Primary, curable diseases: *a*, Melancholia—*a*, Simple melancholia; *β*, melancholia with stupor; *b*, Mania—*a*, Maniacal exaltation; *β*, acute mania; *c*, Stupidity (primary dementia) or curable dementia; *d*, confusional insanity (*Wahnsinn*). 2. Secondary, incurable diseases: *a*, Chronic delusional insanity; *b*, terminal dementia—*a*, with agitation; *β*, with apathy.

II. Conditions of Mental Degeneration.—*a*, Constitutional affective insanity (*folie raisonnante*); *b*, moral insanity; *c*, primary monomania—*a*, With delusions of persecution; *β*, with delusions of ambition; *d*, with imperative conceptions; *e*, insanity from constitutional neuroses—*a*, epileptic; *β*, hysterical; *γ*, hypochondriacal; *f*, periodic insanity (*folie circulaire*).

III. Diseases of the Brain with Mental Disturbances Predominating.—*a*, Paralytic dementia; *b*, cerebral syphilis; *c*, chronic alcoholism; *d*, senile dementia; *e*, acute delirium.

B. Conditions of Arrested Mental Development.—Idiocy and cretinism.

Krafft-Ebing agrees with Schüle in dividing mental diseases into two classes—those of a degenerative nature arising from the development of an hereditary or congenital neurotic tendency, or from injury, sexual or alcoholic excess, etc., and those which occur from what may be called accidental causes in otherwise healthy persons, in whom mental disease would not be anticipated, and from which the late Isaac Ray said that, with sufficient exciting cause, no one has any privilege of exemption. The essential distinction between them was pointed out by Moreau and Morel, and is best stated by Krafft-Ebing:

Degenerative insanity is a constitutional disease arising from slight exciting causes, even physiological conditions (puberty, menstruation, the puerperal state, climacterium), but for the most part from pathological conditions, chiefly hereditary predisposition, injury to the head, acute disease, etc., occurring during development of the sensitive brain, forming often the last in a series of neuropathic disorders, such as spinal irritation, hysteria, hypochondria, epilepsy. The tendency to recovery is slight, and generally there is only temporary return to the primary condition. Relapses and progressive development of graver forms of disease are common. There is progressive hereditary mental degeneration or a strong tendency to appear in descendants in progressively severer form. All forms of the psychoneuroses occur, but of severe type and irregular course, with sudden and rapid changes in the character of the disease, which does not follow any particular course and cannot be definitely classified, rarely ending in dementia, and often lasting in some form through life. The tendency to periodicity is strong. Delusions are chiefly physio-pathological as direct creations of the diseased brain, entirely without apparent cause, to the astonishment of the person and independent of his frame of mind at the time. They appear and disappear, to be replaced by morbid impulses or mental weakness. Delusions are strange, mysterious, monstrous, without possible explanation from the

nature of the disease. There is, for the most part, an inseparable transition from pathological predisposition to actual disease, with a strange mixture of lucidity and diseased mental perversion. Acts are often from impulse. There are sudden outbursts or short attacks; as, for instance, in periodic, hysterical, and epileptic insanity.

In psychoneuroses developed in persons of previously normal brain-function heredity is only a latent predisposing cause. The tendency is to recovery; relapses are infrequent. They are not so readily transmitted to later generations. The disease follows the course of some well-defined type. There is not a tendency to periodicity. Delusions arise chiefly from psychological sources as the result of diseased mental conditions. They are usually not early symptoms, and in general they correspond with the prevailing state of the mind. Delusions correspond with the mental state. The change from health to disease is well defined.

These are the main features of the two classes of mental disease, but the line between them is not a hard and fast one, and it is not seldom impossible to place a particular diseased person definitely in the one or the other.

The objection to all of the classifications of insanity now in use, that they have not an accurate scientific basis, and that a diagnosis must often be delayed or changed as symptoms develop, applies, although in a less degree, to other diseases than of the mind.

HISTORY.—The history of insanity is probably as old as the human race, although its rarity among savage nations at the present day, and its greatest prevalence where there are the widest extremes of wealth and poverty, indicate that it is essentially a disease of the high civilizations. It is found even in the lower animals. It is described in the early writers on medicine from Hippocrates and Plato down. The ancient Egyptians had temples dedicated to Saturn, where they cared for the insane with music and dancing. The Greeks and Romans treated the sick, and probably some of the insane, in rooms adjoining their temples. The monks of Jerusalem built an asylum for the insane of their number in the sixth century. There were several asylums in existence among the Moors in the seventh century, and it is thought that at the time of their invasion of Spain they introduced them into Western Europe. The monks, who were the chief depositaries of medical knowledge in the Middle Ages, treated the insane, as they did to a less extent each other, by flagellations, until St. Vincent de Paul and the Knights of Malta proclaimed insanity a disease and treated it as such. It would be idle to estimate how many were put to the rack, burned, and otherwise maltreated as possessed of the devil or as witches—how many were called prophets or saints.

As late as the last quarter of the last century the insane, when not starving or neglected, were for the most part confined in jails and poor-houses or kept in chains. In Scotland a farmer reputed to be as large as Hercules was said to cure them by severity. In England the practice of exhibiting the inmates of Bethlehem Hospital (Bedlam) to the populace for a small fee was given up only in 1770. In Paris a few of the insane were treated in general hospitals, and the asylums were considered as receptacles for chronic cases, where the attendants, often convicts serving out their time, were allowed to whip them. Van Helmont recommended the sudden immersing of the insane into cold water and keeping them

there for several moments—a remedy brought even to this country. Rush says, as late as 1812, that by the proper application of mild and terrifying modes of punishment (the strait waistcoat, the tranquillizer chair, privation of customary pleasant food, pouring water under the coat-sleeve so that it may descend into the armpits and down the trunk of the body, the shower-bath continued for fifteen or twenty minutes, and a resort to the fear of death) chains will seldom, and the whip never, be required to govern mad people. The intelligent ideas of the Egyptians, Greeks, and Romans regarding insanity were degraded first by the Jewish, and then by the Goth and Vandal, influences in Europe, until, after sixteen centuries of perverse teaching, the stimulus given to all medical work by John Hunter and Bichat, and to humanity by John Howard, prepared the way in France for the philosopher-physician Pinel and his pupil the clinical observer Esquirol. In Italy, Chiaruggi; in Germany, Lange-mann; in England, Tuke; in America, Rush,—began the reform. Up to that time the metaphysicians had nearly usurped the study of insanity. Hospitals for the treatment of curable mental disease were built in Germany besides the asylums for the chronic insane, but still sudden plunges in water, rapid whirling around, and all sorts of shocks and surprises formed a part of the treatment, while Heinroth, Pinel's leading pupil in Germany, thought that all insanity began in vice, that its source was a conscious neglect of God's will, that its best treatment consisted in a pious life, and the only means of prevention to be in the Christian religion. From that time to this, especially since the metaphysical theory of insanity was abandoned, and more particularly during the last quarter of this century, during which the theory of physical disease as the basis of insanity has prevailed, there has been a great and rapid advance in our knowledge of the pathology and treatment of the diseases of the mind, so as to place them beyond the pale of mystery, but on the same footing with other diseases, to be treated on the general principles of common sense and medical science.

PREVALENCE.—It would be idle to attempt to say what proportion of the population was insane at any time or in any country of the world until the most recent years. In Massachusetts in 1820 there were under custody in the one insane asylum in the State 50 patients, or 9.55 in each 100,000 of the population. This number had increased to 11.34 to every 100,000 people in 1830, 61.99 in 1840, 84.97 in 1850, 97.90 in 1855, 122.17 in 1860, 121.24 in 1865, 134.83 in 1870, 138.50 in 1875, and 177.67 in 1880, in six State, one county, one city, one corporate, and six private asylums. The number of the insane in asylums had increased sixty times, and the rate proportionately to the population had augmented more than eighteen times.

In the United States, even after due allowance for the fact that the enumeration of the insane was quite complete for the first time in 1880, the following table shows a recent large increase in their numbers. Of the 91,997 insane reported in 1880, there were 40,942 in lunatic hospitals, 9302 in almshouses without special departments for the insane, and 417 in jails. There are no statistics of the insanity prevalent among the 265,565 Indians living in tribal relations by the enumeration of 1883.

CENSUS OF THE UNITED STATES.

Population.

| Year. | Total. | Native. | Foreign. | White. | Colored. |
|-----------------|------------|------------|-----------|------------|------------------------|
| 1860 | 31,443,321 | 27,304,624 | 4,138,697 | 26,922,537 | 4,441,830 |
| 1870 | 38,558,371 | 32,991,142 | 5,567,229 | 33,589,377 | 4,880,009 ¹ |

INSANE AND IDIOTIC POPULATION IN THE UNITED STATES BY THE CENSUS OF 1880.⁴

| | Total. | Native. | Foreign. | White. | Negro and Mixed. | Native White. | Foreign White. |
|-----------------------------------|---------|---------|----------|---------|------------------|---------------|----------------|
| Insane | 91,997 | 65,651 | 26,346 | 85,840 | 5,998 | 59,600 | 26,240 |
| Idiotic | 76,895 | 72,888 | 4,007 | 67,316 | 9,490 | 63,314 | 4,002 |
| Of unsound mind | 168,892 | 138,539 | 30,353 | 153,156 | 15,488 | 122,914 | 30,242 |
| Population to 1 insane | 545 | 662 | 253 | 505 | 1,097 | 618 | 250 |
| Population to 1 idiotic | 652 | 596 | 1,666 | 644 | 693 | 581 | 1,642 |
| Population to 1 of unsound mind | 297 | 314 | 220 | 283 | 425 | 299 | 217 |

In England and Wales in 1860, with a population of 19,902,713, there were known to the lunacy commissioners 38,058 persons of unsound mind, including the insane, idiots, and imbeciles, or 523 persons to 1 of unsound mind. In 1870 this number had increased to 1 in 411. It seems by the census of 1871, however, that there were 39,567 insane and 29,452 idiots and imbeciles, in all 69,019 of unsound mind, or 1 in 330 of the population. In 1880, with a population of 25,708,666, there were known to the lunacy commissioners 71,191 persons of unsound mind, or 1 to 362 of the population. The census returns of 1881 are not available. The most recent statistics in Ireland indicate 1 person of unsound mind to each 260 of the population by the census, and in Scotland 1 in 362, according to the returns (not complete) to the lunacy commission.

In the following list, after the original States, of which Vermont, Maine, and West Virginia were parts later separated, the others are given in the order of their having been admitted as States to the Union, and finally the eight Territories. The States maintaining slavery up to the time of the civil war are printed in italics. The large proportion of insane persons in the District of Columbia is due to the fact that the gov-

⁴ Total population, 50,155,783; native, 43,475,840; foreign, 6,679,943; white, 43,402,970 (unknown, 148); negro and mixed, 6,580,793; native white, 26,828,640; foreign white, 6,574,330; civilized Indians, 66,407; Chinese, 105,465. Among the Indians there were 53 insane, 84 idiotic, 137, or 1 in 485, distributed over 30 States and Territories; among the Chinese, 105 insane, 5 idiotic, or 1 in 959.

ernment hospital contains so many officers and privates who really belong to the several States; and in California the insane hospitals have been used to a considerable extent by the adjoining States and Territories.

By the United States census of 1880 there was 1 person of unsound mind (insane and idiotic) in the United States to each 297 of the population; in the *District of Columbia*, 1 in 169; Connecticut, 1 in 245; *Delaware*, 313; *Georgia*, 373; *Maryland*, 294; Massachusetts, 249; New Hampshire, 197; New Jersey, 326; New York, 251; *North Carolina*, 270; Pennsylvania, 289; Rhode Island, 301; *South Carolina*, 368; *Virginia*, 290; Vermont, 182; *Kentucky*, 261; *Tennessee*, 259; Ohio, 232; *Louisiana*, 457; Indiana, 239; *Mississippi*, 415; Illinois, 330; *Alabama*, 337; Maine, 226; *Missouri*, 324; *Arkansas*, 371; Michigan, 328; *Florida*, 433; *Texas*, 414; Iowa, 334; Wisconsin, 305; California, 286; Minnesota, 416; Oregon, 312; Kansas, 478; *West Virginia*, 263; Nevada, 1270; Nebraska, 561; Colorado, 1104; Arizona, 1263; Dakota, 839; Idaho, 836; Montana, 529; New Mexico, 434; Utah, 481; Washington, 412; Wyoming, 3464.

The proportion of the enumerated insane in asylums was—*District of Columbia*, 90.6 per cent.; Connecticut, 39; Georgia, 36.8; Maryland, 49.1; Massachusetts, 60.1; New Hampshire, 27.1; New Jersey, 67.8; New York, 57.2; North Carolina, 13.2; Pennsylvania, 36.1; Rhode Island, 57.3; South Carolina, 38.2; Virginia, 45.5; Vermont, 44.7; Kentucky, 50.7; Tennessee, 16; Ohio, 48; Louisiana, 44.9; Indiana, 26; Mississippi, 33.7; Illinois, 42.7; Alabama, 24.5; Maine, 26.1; Missouri, 40.7; Michigan, 41.5; Florida, 30; Texas, 22.3; Iowa, 37.8; Wisconsin, 48.6; California, 80.3; Minnesota, 61.8; Oregon, 65.5; Kansas, 31.9; West Virginia, 40.1; Nebraska, 38; Colorado, 34.3. In Arkansas and in Nevada there was no insane asylum in 1880, and in Delaware the insane were sent to a Pennsylvania asylum or to the almshouse. In the Territories the provisions for the insane are very incomplete.

The statistics just given indicate an enormous increase in the numbers of the insane who become a public charge, and the figures gathered from all countries prove conclusively that more insane people are known to be in existence proportionately to the population from decade to decade. The question naturally arises, Is insanity increasing as fast as appears at first sight to be the case, or is the increase apparent rather than real?

In the first place, the definition of insanity has so widened of later years as to include vastly greater numbers of the population than hitherto. The nice adjustment of social relations in a high order of civilization and greater medical skill make insanity easier of detection. Large numbers of persons now confined would have been considered far from being fit subjects for insane asylums a half century ago. Again, it is hardly a generation ago that we began taking proper care of the insane. Some States have hardly commenced yet, and even in the oldest parts of our country many of unsound mind are kept neglected and squalid in town almshouses or county jails. Wherever humanity has demanded improved accommodations for the insane they have accumulated enormously, from the simple fact that they are protected like children, and kept from dying of neglect, suicide, and exhaustion. In other words, science and humanity have prolonged their lives of illness, in some cases to as much as tenfold their natural length if they had been left to themselves, even where nothing can be done but to prolong their misery. The

more intelligent views now held of insanity as a physical disease rather than a family disgrace have led people to be less backward in reporting their insane relatives as such, while the increasing number of insane asylums and the growing confidence in them have brought many of the insane to notice who formerly would have been concealed in attics and cellars and never mentioned.

Whether or not more persons become insane each year in proportion to the population we have no methods of determining statistically. The mortality returns in Massachusetts for the last five census years show that the deaths from insanity, paralysis, apoplexy, softening of the brain, and unspecified diseases of the brain, including cephalitis, were 12.06 per 10,000 inhabitants in 1860, 14.39 in 1865, 14.95 in 1870, 16.42 in 1875, and 17 in 1880; which would probably indicate an increase, even after allowing for a considerable source of error due to inaccurate diagnoses, imperfect registration, and the influx of a large foreign population. It is claimed that the table on page 111 indicates a direct importation of insane persons from Europe. It is certainly a curious fact that the proportion of idiots and of the insane differs so little in the native population, and that among foreigners the idiots, who could not easily be sent here without being detected and sent back, are less than one-sixth of the number of their insane. But it is also true that the amount of insanity among strangers in a foreign land would naturally be greater than among those who are at home.

The prevalence of insanity as compared with other diseases at the present time may be fairly estimated from the statistics of Massachusetts for twenty years, where there were 604,677 deaths reported, including 2145 from suicide, 1995 from insanity, 1838 from delirium tremens and intemperance. The reported deaths from pulmonary consumption are fifty times as many as from insanity; from diarrhœal diseases, thirty times; from pneumonia, twenty times; from diphtheria, including croup, fifteen times; from scarlet fever, heart disease, and typhoid fever, each eleven times; from accidents, ten times; from cancer, five times; from childbirth and measles, each more than twice as many. The average death-rates reported from insanity per 100,000 inhabitants were 6.24 from 1861-70, and 7.12 from 1871-80, whereas the increase in the number of admissions to Massachusetts insane asylums in the twenty years was from 846 to 1610. The total number of insane people living in the State is less than the number of consumptives dying each year, and far less than the number of syphilitics.

CAUSATION.—It is clear that only a small proportion of the human race is liable to become insane, and one can only wonder that so few brains are overthrown by the multiplicity of causes in modern life which tend to disturb those "invisible thoroughfares of the mind which are the first lurking-places of anguish, mania, and crime." When we come to investigate the causes of mental disease, we find that they are of two kinds—remote or predisposing and immediate or exciting. They are also moral or mental and physical.

Among the predisposing causes heredity includes nearly or quite 75 per cent. of all cases, and is easily first; in considering which not only the immediate parents are to be taken into account, but also the collateral branches, grandparents, uncles, aunts, sisters, brothers, and cousins, for

hereditary insanity often skips one generation, and even appears, sometimes, first in the child, then later in the parent. An insane parent may have several children, of whom some may be exposed to the exciting causes of insanity and become insane, transmitting their disease, intensified or not, to their children, while others may avoid the exciting causes of mental disease, escape insanity, but yet transmit to their children a temperament predisposing them to disorder of the mind, which becomes the starting-point for actual mental disease as soon as the exciting causes are sufficient to develop the taint. If the exciting causes do not appear, however, in that generation, and wise marriages are made, the stock returns to the normal healthy standard and the disease disappears from the family. The same form of disease, too, is frequently not transmitted from parent to child or grandchild, but the neuroses, the psychoneuroses, and the cerebro-psychoses, the degenerative forms and the developed forms, are interchangeable. In the ancestry of insanity we find not only actual cerebro-mental disease, but epilepsy, brain disease due to syphilis, habitual drunkenness, any of the severe neuroses, apoplexy, pulmonary consumption, a closely-allied disease, and suicide. Very often the patient's friends think that there is no hereditary predisposition to mental disease, when the physician trained to study such cases would discover so strong a taint that he would not expect all of several children to escape insanity or some of its allied diseases even in a case where there had not been actual insanity in the family for several generations. For instance, where one parent is habitually using alcoholic liquors to such a degree as never to be drunk, and yet rarely quite himself, with the other a sufferer from one of the severe neuroses or cerebral diseases, a single child from such a marriage might stand a fair chance of inheriting and retaining mental health, but if several children should be born the chances that all would escape mental disorder are few. Again, if one parent were the victim of that intense intellectual strain and moral perversion so often seen in the eager pursuit of position and wealth, and the other, straining to keep up in the race, died early of pulmonary consumption, if there had been in the family cases of convulsions, chorea, apoplexy, or suicide, and if some member were hysterical or, without sufficient external cause, unreasonable, anxious, irritable, full of baseless fears, there might have been no insanity in the family, and yet a tendency to insanity might be transmitted to a considerable proportion of the offspring. On the other hand, the existence of a number of cases of insanity in a family may be due to external or accidental causes, and not indicate any general taint.

It is true that there are families in which insanity occurs where the allied neuroses do not often appear, and that various diseases of the nervous system may be frequent in a stock in which insanity is rare or absent. A person who has recovered from an acute attack of cerebro-mental disorder, if previously healthy and without hereditary predisposition to such diseases, may marry and not transmit to offspring either insanity or any of its allied diseases, while it is not uncommon for an individual seemingly the least liable to mental disease of a whole family to become insane, leaving several brothers and sisters with ill-balanced minds to get through life without breaking down, the morbid energy in the latter case expending itself in irregularities of conduct and of mental operations as fast as it is created, instead of being stored up for occa-

sional outbreaks. The degree to which insanity may be expected to follow any given antecedents can only be estimated very approximately, as the laws of heredity are very little known, and as there is a tendency in nature, so strong that it is constantly asserting itself, to return to the healthy type if it has a chance. But, in general, it may be said that the more individuals of both branches in whom insanity and its allied diseases are found, just so far may a larger proportion of the children be expected to suffer. The character of the particular disease or tendency to disease which is likely to develop from any given antecedents is still a very obscure matter. But the case is often clear enough to justify the remark that if childhood has any rights it has the right to be born healthy.

It must be admitted that geniuses and men of extraordinary talent appear in families tainted with insanity, and, indeed, that comparatively few families have had distinguished men among them for several generations without also showing a considerable number of insane members. Schopenhauer, "mad Jack Byron's son," and Johnson—who said that his inheritance made him mad all his life—are conspicuous examples of this well-known fact; and it is also observed that children and grandchildren of men distinguished for their great intellectual powers are subjects of degenerative mental disorders, or at least are of less than ordinary mental capacity and moral force. The sound and the unsound, too, may exist together in the same mind, each acting in certain ways independently of the other, and cerebro-mental disease not seldom occurs in persons of the highest intellectual attainments. Dean Swift, with his delusion that parts of his body were made of glass; Bishop Butler, tormented all his life by his morbid fancies; Chatterton, committing suicide in an attic; Rousseau, Tasso, Pascal, Comte, Beethoven, Charles Lamb, John Bunyan, the author of *Rab and His Friends*, Schumann, Shelley, Cowper, Swedenborg, and the epileptics Julius Cæsar, Mohammed, and Napoleon,—are only a few of the many illustrations of this law. In the descending scale from insanity we find also crime, drunkenness, and all sorts of moral perversions, which may be its antecedents also. Even a man's self-indulgences may be intensified as mental or moral degeneration in his children. The degenerative processes may go on where there is intellectual stagnation in small communities, with the vices of civilization, as well as in the crowd, producing a large class of persons for whom doctors have only compassion, considering them as invalids although treated as responsible by law and society.

It is difficult to estimate the influence of intermarriage as predisposing to insanity. The history of the early Ptolemies, of numerous savage or uncivilized races, and of many selected cases in the enlightened world may be quoted to show that it is often attended with no evil results; and there are other causes of degeneration in the royal families and aristocracies of Europe and in the cases of individuals where intermarriage of relations has resulted in deterioration of stock. It is, at all events, certain that marriages may be made so as to intensify morbid tendencies or so as to eliminate them—to produce a race of clear heads with sober judgment, or a race part of whom shall be great sufferers from neuralgia or mental pain; another part ill-balanced or explorers in fields of thought and action never tried by calmer intellects, perhaps with now and then at

long intervals a genius ; a third part morbid and brilliant or stupid and imbecile ; and still a fourth part near enough to the normal standard of mental health.

Undoubtedly, a great portion of the mental and nervous disorder commonly attributed to heredity is largely caused or aggravated by imitation and by vicious training of children. Schopenhauer says that the normal man is two-thirds will and one-third intellect—in other words, two-thirds made by education and one-third by inheritance. The intellect is often trained so as to enfeeble the will as well as to hinder the development of the physical man. Self-culture may so degenerate into self-indulgence as to destroy individuality and force ; and mental health, as a rule, depends upon bodily health and the exercise of self-control.

In the uncivilized and half-civilized races of the world insanity is rare ; in the early civilizations the insane perished from neglect, were hanged and burned, starved and died in famine and pestilence, and fell among the foremost in war. Some of the tribes of North American Indians shoot the insane, considering them possessed of evil spirits, while their white neighbors keep them in chains and squalor. Civilization brings better food, clothing, and shelter, and less danger from war, famine, and pestilence than savage or mediæval times. In the struggle for existence, however, physical strength no longer wholly wins the day, but also those faculties that involve great mental and bodily strain in mines, factories, crowded tenements, counting-rooms, offices ; in the eager, excited over-study for prizes or rank in overheated, badly-ventilated schools, and, indeed, in every walk of life. People with marked neuroses, who would have gone to the wall a couple of centuries ago from want of physical strength, now support themselves by indoor light work, marry, and reproduce their kind. Minute division of labor involves monotonous toil and increases the impairment of the body's resistance to mental and nervous strain, and abuse of the nerve-stimulants tea, coffee, tobacco, or, worst of all, alcohol and narcotics, add to the evil. Degeneration due to the reproduction of poor stock is intensified by intermarriage. Luxury, idleness, excesses, syphilis, debility, drunkenness, poverty, disease, and overwork produce vitiated constitutions in which varying types of insanity appear in various nations and climates, but, so far as is known at present, not in very different degree under similar conditions. One of the great problems of the day is whether the many conditions incompatible with health in our crowded populations can be overcome so as to prevent the degeneration going on thereby.

In early life chiefly the degenerative or the hereditary type of insanity occurs, or some modification of it. The prevalent forms coming next are insanity of puberty and adolescence and the curious morbid psychological developments of lying, stealing, running away from home, all sorts of perversity of action and thought—impulse overpowering reason ; often resulting in cure if wisely treated, but not seldom ending in various forms of so-called moral insanity, suicide, epilepsy, hysteria, primary insanity, prostitution, and offences against the laws. It is largely a matter of accident rather than a result of any established principle whether such boys and girls are sent to reformatories and prisons or to insane asylums. In the progressively advancing years of life organic

mental disease and the psychoneuroses are more common, the favorable or unfavorable type of which depends largely upon the degree of degenerative tendency in each case.

The exhaustion and the disturbed cerebral circulation arising from acute and chronic diseases, profound anæmia, or prolonged mental strain, associated with emotional disturbance from any cause, are among the antecedents of insanity. By our asylum reports ill-health is second only to intemperance as an exciting cause of insanity, and ill-health comes probably more largely from poverty than from any other direct cause. Diseases and accidents to the mother during gestation and injuries to the infant's head during parturition may reasonably be supposed to so affect the foetal brain as to predispose to insanity in later life.

Of 18,422 admissions tabulated from reports of Massachusetts asylums, the prevalence of insanity by ages was approximately as follows:

| Age. | Number of Admissions. | Population by Census of 1875. | Admissions per 100,000 of Population. |
|-----------------------------|-----------------------|-------------------------------|---------------------------------------|
| 15 and under | 366 | 312,103 ¹ | 117 |
| 15 to 20 | 1,380 | 165,936 | 832 |
| 20 to 30 | 5,269 | 310,861 | 1695 |
| 30 to 40 | 4,632 | 240,966 | 1922 |
| 40 to 50 | 3,372 | 182,823 | 1789 |
| 50 to 60 | 1,797 | 126,430 | 1421 |
| 60 to 70 | 976 | 79,186 | 1106 |
| 70 to 80 | 382 | 38,283 | 997 |
| Over 80 | 58 | 11,167 | 519 |
| Age not reported | 190 | 10,302 | |
| Total | 18,422 | 1,478,057 ¹ | 1246 |
| Total of all ages | | 1,651,912 | 1115 |

Of the 36,762 persons of unsound mind known to the English lunacy commission in 1859, there were 31,782 paupers, or 86.45 per cent., as compared with 4980, or 13.55 per cent., supported by themselves or their relatives. At the close of 1880, of 73,113 insane, 65,372, or 89.41 per cent., were paupers, and 7741, or 10.59 per cent., were private patients or self-supporting. The increase in the number of the latter from 1859 to 1883 was from 2.53 to 2.96 per 10,000 of the population, or 17 per cent., and of the pauper insane from 16.14 to 25.72, or 59 per cent., while general pauperism had rapidly diminished from 43.7 to 29.5 per 1000 inhabitants.

Similarly, of 9541 admissions to the State hospitals for the insane in Massachusetts from 1871 to 1880 inclusive, there were 4166 State patients, 4050 supported by cities and towns, and 1325 private patients; in other words, 86 per cent. were supported by public charity. Of 7963 admissions in the same time in which the nationality was stated, 4532 were natives and 3431 foreigners, respectively 57 and 43 per cent., whereas by the census of 1875 the natives were 74.64 per cent. of the population, showing more than twice as great a percentage among foreigners (chiefly laborers) as among natives. It is quite clear, therefore, that insanity is more prevalent, or at least increasing more rapidly,

¹ Excluding those under five years of age.

among the lower parts of the social scale than higher up; but it is impossible to say how many people have dropped from higher planes of life to lower.

Although women are probably more predisposed to insanity than men, and men more exposed to its objective causes than women, it is not certain that more insanity occurs in either sex. It is somewhat more prevalent in single and widowed and divorced people than in those married. The period of greatest prevalence is earlier in women than in men.

Insanity prevails not only at a time of life when the strain on mind and body is great, as is shown by the preceding table, but also in those places where the effort is most intense. That fact is well shown in the distribution of insanity over the State in the large and small towns, being greatest where the concentration of population brings with it extremes of poverty and wealth, as indicated by the following table, showing the number of admissions accredited to cities and towns in the McLean, South Boston, and State hospitals for the insane per 100,000 inhabitants from 1871 to 1880, the difference being exaggerated by the proximity of the hospitals and greater ease of commitment in the larger towns:

| Number of Towns. | Population. | Inhabitants by Census of 1875. | Insane Patients. | Insane Patients per 100,000 Inhabitants. |
|------------------|--------------------|--------------------------------|------------------|--|
| 341 | The State | 1,651,912 | 5689 | 344 |
| 1 | Boston | 341,919 | 1987 | 581 |
| 12 | 20,000 to 50,000 . | 405,655 | 1486 | 367 |
| 42 | 5000 to 20,000 . | 367,957 | 1193 | 324 |
| 286 | 5000 and under . | 536,381 | 1023 | 190 |

Of 9381 men and 9041 women admitted to our asylums, 7435 were married, 8193 single, and 1620 widowed or divorced. Of the 9381 males, 2215 were laborers, 1357 farmers, 313 clerks, 62 clergymen, 59 physicians, 43 lawyers, 201 students, of whom 114 were in school. Of 4673 females, 52 were school-girls.

The exciting or immediate causes of insanity are usually so complex that many of the statistics on that point conform to the preconceived views of the various compilers of them, as it is very easy to pick out a few from the many; but out of a large number of persons exposed to the alleged causes of insanity, one can never feel certain how many, nor indeed what, individuals will become insane.

It is not always easy to say how and when the furrows left in the brain by the mental and so-called moral causes of insanity have deepened into actual mental disease. Prolonged emotional and mental strain or severe mental shock often are directly associated with the immediate appearance of insanity. In armies, among people separated from their homes, in prisons, insanity oftener occurs than among the same people at home. Severe grief, disappointment, great and sudden joy or success, chagrin, fear, religious or political excitement, wars, pestilences, domestic or business troubles, poverty, and misfortune are among the commonly-reported moral causes of insanity, as are certain occupations involving steady and monotonous toil, especially if involving mental worry or necessitating unhappy relations.

Of the physical exciting causes of insanity, intemperance in the use of alcohol is easily first: luxury and excess in eating, drinking, and sexual indulgence, especially if associated with overwork or physical inactivity and mental anxiety, are also dangerous. It is difficult to estimate the influence of syphilis except when giving rise to coarse disease of the brain. Masturbation acts as an exciting cause, chiefly by creating a morbid psychical state and by exalting the sensibility of the nervous system, but probably not often, even with the young. Injuries to the brain and nervous system are usually slow in their operation, unlike the severe mental shock which is at once followed by insanity. Pain also, if intense, like great loss of blood, acts slowly by wearing out the powers of resistance, or rapidly by producing delirium.

A relation between pulmonary consumption and mental disease is frequently observed — partly, perhaps, due to general anæmia, in part to circulation of diseased blood in the brain, and partly from tubercular deposits. Other diseases act directly upon the brain and nervous system, as leptomeningitis, pachymeningitis, sclerosis, capillary aneurisms, embolisms, cerebral hemorrhage, tumors, disease of arteries, syphilis, caries, exostosis, abscess, internal otitis, sunstroke; still others by disturbances in the cerebral circulation, as diseases of the heart and kidneys; others by vitiating the blood circulating in the brain, as in the acute stage of febrile disorders; others in some general unknown way, as chorea, hysteria, epilepsy, gout, rheumatism, malaria, pneumonia; and still others during the period of convalescence or of general exhaustion, which is often associated with infectious diseases or chronic disease attended with general anæmia. The more violent and curable psychoses occur at the height of acute diseases, those of longer duration and of less favorable result during convalescence. Among other recognized causes are prolonged and obstinate dyspepsia, the psychological changes, if morbidly developed or attended with accident, at puberty, during pregnancy, at childbirth, during the puerperal state or lactation, and at the climacterium, and rarely various affections of the abdominal and pelvic organs.

Chronic alcoholism produces disease of the small blood-vessels of the brain and the consequences of that condition, causing insanity in a considerable proportion of cases, and almost always some mental impairment. Insanity occurs under conditions of cerebral hyperæmia and of cerebral anæmia, although their relation as cause and effect is very obscure. The habitual use of hasheesh gives rise to a disagreeable form of dementia, and so does opium, but more rarely. The effects of poisoning from iodoform, lead, mercury, bromide of potassium, hydrate of chloral, belladonna, tobacco, when reported as producing insanity, are usually transitory.

Cases have been reported of two persons being exposed to the same causes and having similar attacks of insanity (*folie à deux*), and also of *folie induite* or *folie communiquée*, where several persons have adopted the delusions of a person of influence among them, one of the most remarkable instances of which was the case of the seventeen grammar-school-taught Adventists of Pocasset, who accepted the insane belief of their leader, Freeman, that, like Abraham, he had been commanded by the Lord to kill his child, that she was to rise on the third day after he

had killed her, and that he was to become a great evangelist. So-called epidemic insanity, choreomania, and demonopathy belong in this class.

From untrained, ill-balanced men and women, whose lives are ill regulated, the ranks of the insane are largely filled. Insanity is often the ultimate wreck of a life ill guided, directed chiefly by caprice and passion and weakened by indulgence. In that case it is, like much habitual drunkenness, as much a fault as a disease. The individual will not behave with decency and propriety for so long a time that, finally, especially after the age when the brain begins to fail, he cannot.

SYMPTOMATOLOGY AND COURSE.—The distinguishing symptoms of insanity are mental. In some forms of insanity they are mental only; in others these symptoms are associated with others, such as also occur in diseases not necessarily affecting the mind. The earliest mental symptoms are change of character, increased irritability, less feeling of accountability, a lower moral tone, moral perversion, diminished stability, loss of interest, lessened power of concentration and self-control, impulsive acts, anxiety or the opposite condition of mind, perverted or exaggerated force of the emotions, restlessness, apprehension, sleeplessness, impaired will, slight depression or barely noticeable exhilaration: things and persons seem changed in some vague, unexplained way. There is an alteration in the way in which the person is affected by his surroundings.

The next symptoms are more purely intellectual. Delusions are often at first based upon some fact, and are merged into insane delusions only as the mind, in becoming weakened, loses power of comparison and judgment. Often they arise out of the disordered condition of mind. Hallucinations of any of the special senses, illusions, perverted ideas, mental confusion, mental hyperæsthesia or anæsthesia, delirium, stupor, exaltation, depression, impairment or loss of memory, quickened or dulled conception and perception, increased or diminished intellectual activity and acumen, distorted association of ideas, imperative conceptions, all sorts of anomalies of consciousness and free will, uncontrollable and uncontrolled insane impulses, are common. The intellectual and moral symptoms appear nearly or quite together in very acute disease, and they together increase in intensity, and finally entirely control the individual. Many of the insane recognize the fact of their insanity. Some of them understand the nature of their disease quite well, discuss their cases intelligently, and frequently ask why they, automaton-like, are impelled by a force which they cannot resist to constantly do things which their intelligence and better nature condemn. Not a few are confined in places of safety by their own preference.

The physical symptoms of insanity are perverted sensations of almost every conceivable kind, resulting in depraved instincts and acts, psychomotor excitability, convulsive action, choreic movements, uncontrollable muscular agitation (springing, shouting, swearing, dancing, running, destructive tendencies, etc.), elevation or depression of pulse, respiration, or temperature, loss of appetite, digestive disturbances, pain, fever, tetanic and cataleptic rigidity, paralysis, tremor, ataxia, epileptic seizures, convulsions, muscular contractions, increased or decreased secretions and excretions, disturbances of general nutrition.

The course of the various mental diseases is to a great extent chronic, some forms being incurable from the beginning, others curable to such

an extent that of recent cases from one-half to nine-tenths recover, of whom a considerable proportion remain well to their death. The duration of the mental diseases is from a few days to a lifetime, sometimes not even shortening life. The termination is oftenest in incurable chronicity or dementia, less often in permanent recovery without recurrence, and still less often in death from the first attack. Unfortunately, the essentially incurable and the curable forms of mental disease are classed together in statistics of insanity. While many types are absolutely fatal or certain to end in hopeless chronicity or dementia, others tend to recovery. In some forms relapses and recurrent attacks are to be expected: in others they seldom occur. In many cases there is no more probability of transmission to children than in Bright's disease, and no more likelihood of subsequent attacks than in typhoid fever.

MORBID ANATOMY AND PATHOLOGY.—It is thought by the best observers that insanity depends upon a functional brain disturbance, or at least upon a disordered condition which it is beyond our present power to discover, and that the normal working of the mind depends upon a brain healthy to such an extent that its millions of functional activities, in their endless relations to each other, preserve a state of equilibrium; or, in other words, that the higher centres maintain their power of control over the lower. It is doubtless true that this relation depends in general upon a healthy brain, but it is not yet known to what extent. Disease of the brain or its membranes, apparently slight, often seems to cause insanity, and often there is marked disease without insanity. We certainly cannot place all the pathological conditions found in the brain of a person dying insane in direct causal relation to his insanity. The anæmia observed by Meynert in melancholia and the hyperæmia of maniacal excitement, even if proved to be universal in those conditions, may be only symptoms of the underlying disease or caused by it. It is certain that there are indications of as great anæmia or hyperæmia in other states without insanity.

Insanity in its initial stage does not, as a rule, involve a recognizable deviation from the normal structure of the brain, and the patient may die before such pathological changes are so manifest that we can detect them. But if the disease has been of long standing, in the majority of cases the brain shows evident marks of disease, and there may be found no striking indication to the naked eye of deviation from a healthy condition, when a microscopic examination reveals signs of advanced cerebral disease. The limited knowledge of the cerebral structure and function which pathologists possess, and the consequent difficulty in detecting changes from the healthy state, indicate that the failure to find them is attributable in not a few instances to the fault of the investigator rather than to the nature of the disease. Certain it is that the better acquainted we have become with the anatomy of the brain and with its functions and sensible qualities, and the more thorough and painstaking we have been in our examinations, the rarer it has become to find a case of insanity where no organic changes are observed after death, although it is true that we do not understand all the relations between these changes and the symptoms observed during life.

A large abscess of the brain, a hemorrhage, a tumor, or a wound of the cortex or other portion of the brain, various degrees of inflammation,

meningitis, are sometimes followed by insanity and sometimes not; and we do not yet understand the reason for the difference. Indeed, nearly every pathological condition of the brain known in insanity—in kind, if not in extent and degree—may be found in diseased or injured brains where there has been no mental disease in consequence. There is only one disease, general paralysis of the insane, in which the morbid appearances discoverable after death with our present knowledge bear a definite relation to the most constant manifestations during life. And yet, with pathological changes so similar that we are not able to detect their essential difference, the mental symptoms of the first stage of general paralysis may be most various. Rosenbach has found in the brains of starved dogs and guinea-pigs as extensive changes as in well-marked primary dementia, in which the pathological conditions are more extensive than in any other form of acute insanity.¹ That is to say, when we have discovered and described all the morbid appearances in the brain of an insane person we have taken only the first step in accounting for his insanity.

The localization of many of the cerebral functions, the discovery of a psychomotor tract, and the constant accessions to our knowledge of the physiology of the brain are throwing much light on the subject. But all efforts to localize the intellectual and moral functions of the brain, except generally to agree with the teachings of a century ago and to place them for the most part in the anterior and antero-lateral portions of the cortex, have thus far failed of success, the most careful observers still thinking that local lesions when apparently causing insanity do so by injuring the action of the brain as a whole, and not of any particular part.

In some cases of insanity, with never anything like acute disease, where death occurs from the weakness of old age or some intercurrent malady, the brain does not present any recognizable difference from those of sane people whose brains have worn out with their bodies. In those forms of mental disease where changes are found, the most important and constant are in the cortex of the brain, especially in the fore, upper, and middle parts of the periphery, involving usually also the membranes. In beginning acute mania the condition of the blood affecting the brain or the pathological changes are probably as nearly identical with those in the acute stage of pneumonia, certain forms of typhoid fever, cerebro-spinal meningitis, and other diseases as the symptoms of the mania are now and then difficult to differentiate from those of the other diseases just mentioned. In rheumatism, syphilis, malarial poisoning, and Bright's disease with mania we find no distinctive pathological conditions to account for the maniacal symptoms.

If asked whether there is a fixed lesion of the brain or any of its parts corresponding to given psychological changes, we should be obliged to say no, except in the case of incurable dementia. If asked whether there are important morbid changes corresponding with all cases of insanity, we can only say yes, sooner or later, in the majority of cases, and that there are certain destructive lesions, chiefly inflammatory, atrophic, and degenerative, which invariably mean marked deterioration of the mind. As regards diseases of other organs than the brain, the insane, like the sane, die of all of them, and in especially large numbers of pulmonary consumption.

¹ *Centralblatt für Nerv. Psych. und ger. Med.*, 1884, p. 33.

Insanity may, both in its acute and chronic form, be the result or symptom of simple anomalous excitation or nutrition of the brain or of inhibition of some of its portions, without any change in its gross appearance which can be detected by our present methods of research. In the majority of cases there are found diseased conditions which become more manifest the longer the duration of the disease, appearing for the most part in the blood-vessels, pia mater, and cortex of the brain, but also in the medullary portion, many of which are recognized only in their late stages. In the functional mental diseases there is no characteristic lesion of the brain as yet recognizable, even in the latest stages, more than is to be found in the brains of persons dying from other causes. When apparently local injuries or diseases cause insanity, they probably do so through a general disturbance of the brain or through diffuse disease resulting therefrom and for the most part affecting both hemispheres. The molecular, chemical, anatomical, physiological, pathological, or physical changes in the brain which give rise to insanity, and their relation to the grosser pathological conditions of the brain, are still not clearly made out.

In terminal dementia, especially in the last stage of paralytic dementia, nearly every tissue and organ of the body may be found to have undergone pathological changes, of which by far the greater portion is secondary to disease of the brain; and it is impossible to say how much of the brain lesions in these and other conditions of mental unsoundness is secondary to the disease or an accidental complication.

DIAGNOSIS.—In the diagnosis of insanity the physician assumes a responsibility for which he is liable under the common law. It is important, therefore, to avoid mistakes as far as possible. In the majority of cases the patient's unsoundness of mind is evident before he is brought to the doctor, but in not a few the symptoms are obscure, and they are often rendered more difficult of correct understanding and appreciation by the deception or reticence of the patient and by the prejudices of his friends.

First, before seeing the patient it is well to get from his family, friends, and physician a full knowledge of his natural state, all the facts known to them relating to strange behavior, delusions, etc., as they give most useful hints with regard to the method of examination. Apparent familiarity with an insane person's delusions will often secure their immediate acknowledgment. In a case of any obscurity or where there is doubt that other causes than insanity may have produced the unusual behavior, and particularly if any legal steps are to be taken regarding guardianship, restriction of liberty, commitment to an asylum, validity of wills and contracts, capacity to manage property, marriage, etc., it is imperative that both sides of the question be fully heard before any positive opinion is given. After the patient's confidence has been gained in general conversation, during which his appearance, manner, and mental condition as to intelligence, coherence, memory, judgment, perception, and capacity may be noted and compared with his normal standard, he should be examined carefully for any external evidence of lack of development or of injuries to the head. As in all other diseases, the condition of every organ of the body should be noted; a complete diagnosis should be made. The expression of the face often indicates such excessive excitement, gloom, stupor, suspicion, or fear as must be due to insanity alone.

Throughout the examination the questions and manner of the physician should be such as to avoid suggesting unpleasant ideas or associations to the patient. The matter of suicide should never be first mentioned by the questioner, and not seldom he does best who listens most and lets his patient disclose his morbid ideas and impulses, as he will frequently be led to do, if at all, by the manifestation of interest and sympathy, and of knowledge of the symptoms of the disease in hand, on the part of the physician. He often gets enough for his purpose without getting the whole story, upon which it sometimes does harm, or at least is not best, that the patient should dwell. In the diagnosis of mental disease, however, as well as in estimating responsibility, the fact must be borne in mind that a controlling delusion may be concealed for months or even years, and that the symptoms and mental condition of insane people vary so much at different times that it may be quite possible to get distinct evidence of unsoundness of mind at one time and not at another. The power of self-control is also liable to the same variation or alternation.

If the patient has no reason for simulation, it is commonly best to tell him the object of the examination. The family history should be learned from others, as questioning the patient on these points is apt to put him in a train of thought unfavorable to a hopeful view of his own case. After full personal questions concerning himself and his environment, one can usually tell whether there are unreasonable suspicions, violent impulses, perverted feelings with regard to his family, delusions, hallucinations, or illusions. A delusion's existence must often be accepted, however, from the behavior of the patient and from the statements of those about him. Hallucinations of hearing must sometimes be inferred from the attitude of listening to imagined voices; and prolonged observation under circumstances such that the patient does not know that he is watched will often settle the question of his insanity when other means have failed. A careful examination should, of course, be always made for the physical and rational signs of disease. In the differential diagnosis care must be used not to mistake for insanity the acute diseases typhoid fever, meningitis, smallpox before the period of eruption, pneumonia, cerebro-spinal meningitis, narcotism or delirium from drugs, and alcoholism—errors which have been made, and which can be avoided by deferring one's opinion for a sufficient time.

The detection of simulation is more difficult, especially as the insane sometimes feign insanity for a purpose, or, on the other hand, accuse themselves of wrong acts which they never committed. In general, it may be said that sane persons pretending to be insane very much overdo their part, do not make their symptoms conform to any recognized type of disease, and have a strong motive for their deception, as well as for the act for which they wish to be considered irresponsible. Their insanity first appears after the deed; they are exhausted by their efforts to seem mad, and appear quite sane if watched when they think that they are unobserved. A crime performed without accomplices, with no plan or a silly one for escape, and with no sane motive, is usually itself evidence of insanity. On the other hand, people partly demented by chronic insanity often commit crimes with all the method and motive of the criminal. In not a few cases, especially when the fact or not of impaired intellect cannot be decided by comparison with a previous condition, the question of

insanity, or at least of responsibility, will be beyond human wisdom. A correct diagnosis can, of course, not be made without a familiarity with the various forms of mental disease; and insanity is now so well understood that a sufficient examination of an insane person should develop the clinical history of some known type of disease in nearly every case.

Little has been said of the physical evidences of insanity, because there is little to say. Conditions of mental torpor, depression, and excitement are associated with the physical manifestations which we would naturally expect in those mental states. Coarse brain disease with insanity or without may have identical physical signs; paralytic dementia is the only disease in which corporeal indications really assist in forming a diagnosis.

A family predisposition to mental disease does not materially affect the question of fact whether a given individual is insane or not, except that in a doubtful case it adds to the probability of insanity, and is thus far a factor of importance as corroborating other evidences of an unsound mind.

PROGNOSIS.—The prognosis in insanity depends first upon the type of disease, mania, melancholia, and some forms attended with confusion and stupor being the most curable; the forms attended with systematized delusions or with periodicity which is not dependent upon menstruation, folie circulaire, and moral insanity rarely so, and the organic brain diseases, congenital insanity, and confirmed primary delusional insanity (monomania) hopeless. The acute forms are far more curable than those of a subacute type: 60 per cent. of the cures in insanity occur in the first half year of treatment, 25 per cent. in the second half, and 2.5 per cent. in the second year, roughly speaking. In chronic cases a reported cure is most commonly only a remission, and after several years of existence insanity is generally incurable, although rare cases of cure in mania have been reported after even from six to fourteen years of treatment, and in melancholia after twelve years. So long as there is no permanent dementia and there are distinct intervals of mental clearness, no matter how short or how far apart, there is hope of final recovery in the curable mental diseases.

People of sound families, with insanity of an acute type arising from physical causes, often make such speedy and complete recovery as to justify their subsequent marrying if they wish, while those of unstable nervous organization recover more slowly and oftener relapse. Insanity from so-called moral causes, too, is of more unfavorable outlook than if from the physical causes, if we exclude organic brain disease. A person with good physical education, excellent mental training, and self-control is more likely to get well than one with a vicious bringing up. The ages of maturity and middle years are most favorable to complete recovery. In women there are more first cures and more relapses, according to Krafft-Ebing. In general, the mortality of the insane in asylums is about four times that of the sane of all ages, or approximately six times that of the sane at the ages when insanity prevails.

Prolonged stupor, profound incoherence, loss of memory, and moral debasement are unfavorable symptoms, unless quite acute, of short duration, or occurring after the rapid subsidence of acute symptoms. Hallucinations of hearing, and to a less extent of sight, impulses to violence, and especially systematized delusions, are grave indications. Paralysis,

epilepsy, and convulsions usually mean chronicity or death. Extensive disease of the heart, kidneys, or lungs, confirmed dyspepsia, especially of alcoholic origin, and a previous history of syphilis, seriously affect the prospects of recovery. If there is actual cause for self-accusation, if the knowledge of wrong-doing is added to the morbid mental state, the period of convalescence is apt to be much retarded, or even recovery is prevented, by the difficulty of establishing a healthy reaction. Even an irresponsible act is often magnified into so depressing an influence as to prevent restoration to health, as in the case of those who have injured or killed members of their family.

Of 9689 persons admitted into the Worcester Insane Asylum¹ during fifty years ending September, 1881, of whom 1083 had been in other asylums, 35.49 per cent. were discharged well, 26.61 per cent. improved, 17.71 per cent. not improved, 0.5 per cent. not insane, and 14.85 per cent. died. Of those discharged, 25.41 per cent. were readmitted, and of 798 discharged recovered, with regard to whom inquiries were made, 156 were reported well at the time of replying, 197 as having died sane, 30 committed suicide, 162 relapsed and died, 94 relapsed and were alive, 30 were in hospitals or almshouses insane, and of 129 no information was got. Out of 798, there were 316, or 39.6 per cent., known to have become insane again or to have committed suicide. Of 1966 second admissions, 668 recovered; of 607 third, 263; of 261 fourth, 119; of 132 fifth, 70; of 70 sixth, 42; of 48 seventh, 30; of 37 eighth, 21; of 30 ninth, 19; of 26 tenth, 15; of 23 eleventh, 11; of 18 twelfth, 11; of 15 thirteenth, 10; of 12 fourteenth, 8; of 8 fifteenth, 5; of 4 sixteenth and seventeenth, 3; of 4 eighteenth, 2; of 2 nineteenth, 1, who was admitted and discharged well twenty-three times.

Thurnam's statistics, that one-half of the recent cases of insanity treated in asylums recover, and that of the recovered only two-fifths remain so, receive constant confirmation. There is a considerable proportion of the inmates of asylums whose brain-condition is so unstable that they come in and go out frequently. Their brains are unstable, too, in the little affairs of life, and many of the nominally cured remain comfortable only by being shielded from sources of physical wear and mental worry. It is impossible to get statistics of the curability of mental diseases properly treated outside of asylums, but the results would probably be more favorable than those just quoted, partly from the greater chances of cure in the mild cases and in those acute cases which can be kept at home, or at least do not require hospital treatment.

It is difficult to form an opinion as to the probability of subsequent attacks in those who have recovered from any of the curable forms of mental disease. The same constitution, of course, remains as that which predisposed the individual to the first attack, and no one can look far enough into the future to predict the influences which will be brought to bear upon any given person for a considerable period of time. If they are favorable for preserving mental health, the chances of escaping mental disorder in the future are very much greater than if the occupation which must be pursued and the life which must be led predispose to bodily exhaustion, anxiety, and brain-worry. If the disease first appeared under slight exciting causes, it will not often be possible to

¹ *Forty-ninth Annual Report*, including tables by John G. Park, Medical Superintendent.

avoid similar conditions again, and some forms of insanity are characterized by relapses and recurrent attacks.

Of the persons reported recovered from mental disease, a large proportion fail to recover in the sense of being fully themselves again. There is left some change of character, no matter how slight, some moral perversion, irritability, instability, impaired will, lessened power of self-control, diminished mental capacity—some lowering of the intellectual or moral standard, some deterioration of some kind.

TREATMENT.—Not long after Leuret recommended and practised severe discipline in the treatment of the insane a case was reported at the Medical Congress in Naples (1845) where douches, setons, blisters, bleedings, internal medication, shocks, terror, harsh discipline—nothing succeeded in restoring to sanity a woman become insane three months after her confinement. There probably are places where similar methods are practised at the present day, and yet it is not unreasonable to suppose that the very treatment used is sufficient to render incurable patients who might otherwise get well. The modern management of mental disease by rest, diet, baths, fresh air, occupation, diversion, change of scene, no more medicine than is absolutely necessary, and the least restraint possible—in a word, improving the patient's general condition, meeting the indications of his disease, diverting his mind from its morbid thoughts, or putting the brain in a splint, so to speak, as each case demands—gives much better results, the value of which is much diminished by the enormous increase in the size of our asylums and the great aggregation in them of diseased persons in all stages of insanity.

In twenty American asylums, the statistics of which have been analyzed by Pliny Earle in his paper on the *Curability of Insanity*, the average diminution of reported recoveries for about twenty-five years has been from 46.08 to 34.26 per cent. annually of cases admitted, and in the Massachusetts State asylums from 25.95 to 22.25 per cent. of 3371 persons admitted from October, 1879, to October, 1882. The prospect of treatment of insanity does not, from these figures, look very hopeful, and it must be conceded that there is in the proportionate number of reported recoveries a decrease which it is important should be explained. It is undoubtedly true that a larger number of the chronic and quiet incurable insane are sent to the asylums now than formerly, thereby diminishing the curable proportion. The character of the asylums, too, has changed from being small, easily-managed institutions to overgrown affairs, crowded with so many incurables that the duties of the superintendents have become largely administrative, and the medical treatment of the sick has been driven to a subordinate position. Medical officers, too, are more cautious in using the word cured after experience has shown them how many reported cures are only remissions.

In treating insanity, even more than any other disease, the fact must be borne in mind that one is treating a diseased person; and indeed it is often necessary to treat a whole family of persons predisposed to insanity in giving directions for one actually insane. There probably has been no time during the last quarter of a century when there was more uncertainty in the minds of the medical profession regarding the best treatment for patients suffering from curable mental diseases than at present. Twenty-five years ago the almost universally-accepted practice was to send

them to an insane asylum with as little delay as possible, without much regard to the character and duration of their disease. Twenty years ago, in the medical school the professor of obstetrics advised sending all well-marked cases of puerperal insanity early to the hospitals for the insane, and only a few years later Godding, then superintendent of the asylum at Taunton, advised that patients with puerperal insanity be kept at home until every available resource but the asylum had been tried without success.¹ Meynert lectures to his classes in Vienna that in every case there is a disadvantage in sending curable insane persons to asylums, although it is often a necessity to do so. Maudsley thinks that a large proportion of the curable insane can be treated to best advantage either at home or in small private asylums or houses; while Bucknill says that by home treatment more cases would be cured than with our present methods. The late Isaac Ray summed up his vast experience in the treatment of the insane by saying that it cannot be shown that the introduction of insane asylums has added anything to the curability of insanity, much as they are to be praised from the humanitarian point of view. According to the statistics of Pliny Earle—to which the only objection we can make is that they are so exhaustive and conclusive that we cannot controvert them—the permanent curability of mental diseases in asylums for the insane is not only small, but decreasing.

Part of the results obtained by Earle may be due to the fact that curable cases are more treated at home now than formerly, that the degenerative types of insanity are more common, and that in our cleaning up and civilizing processes we are not only driving out filth diseases, but letting in disorders due to greater efforts and more intense struggles for the kind of existence which modern life demands. But it is also true that in enlarging our asylums, as we have been compelled to do, we have lost something in personal care of patients, and that we have increased the depressing influences of large masses of sick people to such an extent as to involve serious disadvantages in their treatment. It is a matter of common observation that some insane people do well at home, others away from home, and others in asylums—that some do badly in asylums, and quickly get well if discharged, and that others, after continually going down at home, immediately improve upon being sent to an asylum. There seems, however, to be no fixed rule in individuals, and certainly there is very far from unanimity of opinion among alienists generally as to the conditions for home treatment or removal from home or sequestration in asylums, except, of course, that few men of experience would take the responsibility of keeping out of asylums persons with alcoholic insanity or with delusions of persecution, or cases of violence and delirium, or any insane patients under conditions involving danger to the community or to individuals, although it is often a matter of extreme difficulty to decide when restraint becomes necessary or justifiable.

I have selected from a large number a few cases where I have acted contrary to the usually accepted views as to indications for removal from home, and with such success that I am led more and more each year to rather widen than narrow the lines within which home treatment seems to me desirable.

Case I.—Mr. ———, age 20, of sound constitution and without

¹ *Boston Medical and Surgical Journal*, vol. xci. p. 317.

marked hereditary tendency to disease, although several members of his family are people of very little force. The patient had masturbated in college, as many boys do, and was compelled to give up his studies upon his father's failure in business. An attack of slowly-advancing melancholia developed, for which he was sent to the farm of a relative in the South without improvement, so that he returned home at the end of a year in pronounced acute melancholia. He secreted himself in a marsh not far from home, where he was by accident found bleeding freely from the radial artery, which he had cut to kill himself. He had the usual delusions of the disease. He thought the world was all wrong, that he had committed great crimes—the unpardonable sin—and that there was nothing but destruction before him and his family. He was desperately suicidal. The circumstances giving rise to his disease and the associations of his delusions were entirely connected with his home and members of his family. His people could not afford to hire a nurse, but his three brothers and one cousin were only partly employed, and they agreed to take care of him. The treatment was tonic and supporting, with plenty of sleep, food and outdoor exercise, with careful attention to daily details of life, arranging it as to amusements, occupation, etc. etc. from day to day to suit his condition, and with absolute watchfulness day and night to prevent suicide. He remained in the home where his disease arose, and he was taken care of by the people most actively associated with his delusions. He made a rapid and perfect recovery, and is now very successful in his work as a professional man.

Case II.—Miss ———, age 35, a sound, healthy woman, without any known hereditary predisposition to disease. Without any assignable cause, except a moderate amount of overwork and steady home-life without sufficient recreation, she became very ill with acute melancholia, much mental confusion, very varied delusions that the world was all wrong, her friends distorted and changed, and herself so great a sinner that she could not escape everlasting damnation. Her most constant and distressing delusion was that people were constantly lying in wait to kill her and her mother and her sisters. When I saw her she was taking large quantities of hydrate of chloral and bromide of potassium, which were at once stopped. With plenty of food, fresh air, exercise, rest, malt, and cod-liver oil she slept well. She was first put under the care of a professional nurse, who was not liked by the family, and I then decided to let the mother and sisters assume full charge. She was watched with unremitting care day and night, and yet managed to make three attempts at suicide, which of course were not successful. She made a rapid and most perfect recovery, and is still perfectly well.

Case III.—A letter-carrier about 25 years old, without known hereditary tendency to disease, under-fed, over-tired, and worried, broke down with pronounced mania of the simple type, without marked delirium or delusions. He was much exhilarated, often excited, rarely noisy, and, as he had no delusions, he was not dangerous. He was somewhat troublesome, and I feared that his disease might become more active, and so I recommended his removal to an asylum, to which his friends fortunately refused to consent. He became progressively worse, but still not maniacal or delirious. He had no specific insane delusions, but he had a generally exalted notion about all the events of life and his own affairs. His

surroundings were not conducive to quiet, as he lived in the noisy part of the city, and his associations were those under the influence of which his disease appeared. But he made a most excellent recovery, and resumed his work with only a year's interruption.

Case IV.—A healthy young woman, without hereditary predisposition to insanity, confined with her first child. Her delivery was not attended with any especial difficulty, and she made rapid progress toward health and strength until the beginning of the third week, when a slight change of character was noticed which soon developed into active mania. She was delirious, profane, obscene, filthy in her habits, and filled with delusions regarding herself, her family, and her surroundings. She had a great aversion to her infant, and often did not know the several members of her household. Hers was as violent a case of puerperal mania as I have ever seen in an insane asylum. She was naturally not very strong, however, and people could always be near enough at hand to prevent her doing any harm to herself or others. Her infant was kept out of her sight most of the time for five months, and all of the time for many weeks. The usual treatment was adopted, an excellent recovery was made in six months, at the end of a year strength was restored, and the patient remains quite well now.

Case V. was quite similar to the last, except that the disease was melancholia, and that the patient had tried to kill herself and her infant before I saw her. She made a complete recovery. Both cases were taken care of in their own homes, and for the most part by members of their own families.

I have reported these cases with as little detail as possible to illustrate the point which I have insisted upon for several years, that many cases at least of mental disease are to be treated precisely like typhoid fever or rheumatism or a broken leg, so far as removal from home is concerned, and that home-associations are no more harmful in properly-selected cases than in pneumonia or phthisis. I do not mean, however, that the patient should not be under the most careful treatment. On the contrary, the little details of medical care are fully as important as in early Pott's disease or beginning inflammation of the hip-joint. But it is often difficult to decide what cases should be best treated at home, what by slow travel or removal to other places than home, and what in asylums.

The objections to asylum treatment, when it is not absolutely necessary, are very great. On the other hand, the advantages that asylums possess for supervision and control are so obvious that they must continue by far the best means of treating the vast majority of cases of incurable insanity, and a large proportion of those in which a cure may be reasonably expected. The exigencies of many cases demand them. If, however, it can be shown that the aggregation of invalids in them is unfavorable to the best chances of recovery, and if, as I think is the case, many of the restraints and restrictions now common in them are unnecessary—for many of the patients, to say the least—the deduction is clear that a change must be made in asylum construction and management to correspond to these views. A common depressing influence in the treatment of mental disease is the fact that the patient remembers some member of the family who has had to go to an insane asylum, and fears the same fate for himself, or after one commitment and recovery fears that he may

have a relapse and be obliged to enter an asylum again. I am quite sure that a considerable number of the recovered patients of insane asylums who commit suicide do so from this dread; which is not altogether unnatural, as the tendency there is downward, so that the patient, as he in the progress of his disease more and more loses self-control and power of decent behavior, is progressively dropped into lower wards, with more disorderly or demented patients, at a time when all the surrounding influences should be, on the contrary, of a tendency to lift up. On the other hand, many who recognize their infirmity wish to be taken away from old friends and associations, and prefer the seclusion of an asylum, which is their best home.

The more acute the disease, the more likely it is to be of not long duration, and, as a rule, the easier it is to treat it without removal from home, except in cases of great violence. The question whether home-influences are benefiting or injuring an individual patient must often be settled by experiment. It is a great comfort to many of the insane to see their friends, no matter how seldom, at times when they feel that they need their support and influence; and this is impossible unless the friends are near at hand. There are cases in which familiar scenes and faces and voices reassure the patient when delirium subsides, and during a short interval of comparative mental clearness their sedative influence is great as compared with the confusion and worry of trying to understand the new surroundings of a hospital ward or the sight of strange people and the sound of unknown voices. The mere fact of delusions being connected with the home-surroundings and members of the family is not so important as the character of the delusions; and the influence of the relatives is often most salutary, even when the patient has most distressing thoughts concerning them or even when he is too insane to be always sure of their identity. If the insanity arises in a violent emotional shock, and home sights and surroundings recall and arouse the mental pain, as is the rule in such cases, recovery usually depends upon removal from home. The matter of suicide where there are means of proper watching does not influence me in my decision, as I think that the dangers of self-destruction are fully as great in asylums as outside with sufficient care, whereas the stimulus to the patient to kill himself from both insane and sane motives is greater the more he is surrounded with depressing influences. On the other hand, it not seldom happens that the diversity of sights in the hospital, the routine, the varied events of the day, the amusements, the walks, the drives, even the discomforts and annoyances, serve to distract the patient's mind from his delusions better than the same result can be accomplished under the pleasant influences at home, while a natural feeling of self-respect prevents those who have power of self-control from giving way to their impulses before strangers, especially when they know that such conduct will take them to a lower ward with less agreeable associates.

There is no doubt, however, that home-treatment of the insane in the majority of cases is synonymous with neglect of all those minute attentions to details that make the difference between recovery and chronic mental disease. Home-associations often act upon the insane mind like frequent passive motion to a diseased or fractured hip; the relatives of the insane patient oftener than not share with him a common inheritance

of an unstable mental organization, and will not be judicious in their treatment of him, or they cannot be subjected to the risk of becoming insane themselves in taking care of an insane brother or parent; and it is seldom that a private house away from home can be converted into a hospital, as it must be for the treatment of an insane person. One of the greatest difficulties in the home-treatment of the insane is during the many months of slow convalescence, when it is difficult to prevent a too early resumption of cares or work or methods of life prejudicial to complete restoration to health; so that in that stage of the disease, if in no other, removal from the familiar and usual surroundings of the patient will usually be quite necessary. The small private hospitals, with all their many and obvious advantages, always have been, and inevitably must be, chiefly devoted to wealthy patients who wish for a home where they can have medical supervision, rather than curative institutions for any large number of persons; and there is not enough going on in them to sufficiently occupy the attention of certain curable patients who must be removed from home, although they are well adapted to those who need quiet and seclusion chiefly. The larger hospitals, with their large staff of skilled officers and nurses, and with all their appliances for recreation or rest, amusements or occupation, discipline or gentle support, must be our chief means for treating the insane. They are indispensable for a large number of the insane who are of such unstable mental equilibrium that a little over-exertion or a trifling deviation from a carefully regulated routine throws them off their balance; and they must be used, temporarily at least, for many of the incurable or partially curable insane who need a place and an opportunity to learn self-control and self-management. Enormous advances have been made in the construction and management of hospitals for the insane, more especially in the last fifteen years. We see it everywhere. But the greatest need, of opportunities to combine advantages of the asylum treatment with the benefits of home-comforts, to place sick people where the influences surrounding them will be healthy, and where there are not so many harmful as well as useless restrictions upon liberty, and so many morbid associations, is as yet entirely unfilled in this country. The question of the best, or even of an improved, organization for our insane asylums is too wide a subject to be discussed here. That our present system tends to make the medical staff narrow if they are appointed to their duties without previous broad training and experience or for political reasons, is a self-evident proposition; and yet there are manifest objections to just such a visiting staff as is customary in general hospitals.

As Maudsley says, squalor in an attic with liberty is better than being locked up in a palace with luxury. Many of the insane share that feeling with their sane brothers. To not a few it makes the difference between recovering their mental health and lapsing into incurable dementia. Many would voluntarily consent to remain in places less distasteful to them. If we could separate them into classes, as Mr. Mould¹ has done in England by buying or hiring ordinary dwellings one or two miles even from his asylum, we could have separate houses with open doors or shut, as the case demands, for those who require them, and reserve the

¹ *Presidential Address at the Annual Meeting of the British Medico-Psychological Society, October, 1880.*

associated halls and large buildings for a different class. Mr. Mould has not applied his own system to those cases which need it the most, the curable insane, except to a very moderate degree.

It is not often that the physician is called, or his advice heeded if given, in the early stages of mental disease, and the first symptoms are by no means easy to differentiate from the less harmful results of mental strain. If there be, however, sufficient loss of equilibrium to suggest the question of beginning insanity, it is of course better to take the safer way and recommend removal of all sources of irritation, and to advise rest, sleep, simple food, attention to the general laws of health, outdoor life, and change of scene for a sufficient length of time to restore the mental poise, avoiding narcotics and sedatives as far as possible, and keeping the patient with a safe adviser or within easy reach of one. In many cases, especially of young persons, this may involve a radical change in their choice of a profession and whole plans of life. If the question of marriage comes up in these cases before the physician as to preventing further developments of threatened disorder, it can only be said that what may be well for the individual is not always best for society. A few years' delay will usually give time for the question to settle itself.

When insanity has actually appeared the same rules should govern its management as in other diseases. If, like smallpox and diphtheria, it is a great source of danger to others, the patient should be put in a safe place; if, like typhoid fever arising from bad drainage, its cure depends upon the removal of a given cause, the patient must leave the infected locality or have the cause displaced; if, like rheumatism in a damp cellar, it can be treated successfully only under different conditions, the patient must be removed; and if poverty or other conditions prevent the best possible treatment, the next best practicable plan must be followed.

The first question which comes up in the care of the insane is with regard to removal from home and commitment to an asylum; and here a great many points must be taken into consideration. It is not always that a home can be accommodated to the use of an insane member of the family. There are not many in which there can be proper quiet and seclusion without depriving the patient of that abundance of fresh air and outdoor exercise which is so often required in treatment. Frequently those nearest to him irritate him to the last degree, or he has some aversion or delusion in regard to them rendering their presence injurious. If the delusions and impulses of a patient are not such as to endanger the lives of the household, his violence and excitement and uneasiness or melancholia may make life simply intolerable to his relatives, or his exactions may be exhausting to their strength and his constant presence a means of making still others insane. His noise may disturb a whole neighborhood. His vagaries may require control, his indecencies concealment, his enfeeblement help more than can be sufficiently given outside of a hospital, his general condition more judicious care than his friends can command, and his example may have a pernicious effect upon children growing up with an insane diathesis. In many people a long time insane much of their vicious conduct is due to habit or to tendencies which they cannot or will not control without the steady, kind discipline which cannot be got at home.

A man with delusions by virtue of which he thinks that some one is

plotting to ruin or kill him is apt to commit murder; a mother who believes that the world is going to ruin and her children to torture may be expected to put herself and them out of misery; a demented woman chops off her infant's head because its cries disturb her; and the maniac's delirium or epileptic's fury drives him into any horrible act. Such people need to be watched always by some person or persons fully able to prevent their doing harm, which in many cases can only be done, with any reasonable degree of liberty to the patient, in a hospital for the insane. If the danger is obviated by removal of certain persons—children, for instance—or if watching by nurses serves the purpose, and there are no other objections to such a course, there are cases in which the chances of cure are more if the patient remains at home whenever the disease pursues an acute course. Most of the insane, however, have passed the curable stage; the majority need the moral support and freedom from responsibility or the regular life and regimen of a hospital; and a large proportion of the cases following a subacute or chronic course must be removed from home. The expense attendant upon the safe treatment of mental disease in a private house is entirely beyond the means of most families, just as they cannot send their consumptives to Colorado or France, and so the hospital becomes a necessity. Except in dangerous cases, however, the hospital should never be hastily decided upon. A little delay does not diminish the patient's chances of recovery, and may show that the attack is only transient, whereas removal to a strange place might aggravate the disease and increase its duration. It is particularly important not to choose an unfavorable time to commit an insane person to an asylum, and thereby add to discouraging conditions already existing an additional source of despair at a time when every influence should be as elevating and cheering as possible. In most cases, especially if there is a suicidal or homicidal tendency, it is best, when removal to an asylum has been decided to be necessary, not to argue the question with the patient, but to explain why it must be done, and then do it without delay.

The law provides the methods of commitment to asylums. They are so different in the different States that they cannot be discussed here.¹ The one rule holds good everywhere, however—that it is far better to use force than deception in sending the insane from home to asylums, and that the cases are very few in treating the insane in or out of asylums where deception is either justifiable or wise. A second safe rule is that a person of unsound mind is always a source, immediate or remote, of more or less danger.

Commitment to an asylum means so much that safeguards against improper action should provide careful examination of the case by competent physicians, as little restraint as is required by safety, good medical treatment in the hospital, thorough supervision by experienced persons on the part of the state, safe-keeping of the dangerous patients, and easy removal of those who have recovered or who may be sent out to their own advantage. In too many States confinement in an asylum means that two physicians, or even one, who may know little or much of insanity, think it best, and removal depends upon the word of one man,

¹ An abstract of the various laws may be found in the appendix to the American edition of Clouston's *Clinical Lectures on Mental Diseases*.

the superintendent. Once in the asylum, the best practice of the present day should be followed—namely, to allow free communication and visits from friends until it is shown that they do harm, to multiply cheerful and natural influences to the last degree, to furnish rest, exercise, occupation, or recreation as each case requires, and to remove all that is morbid and disagreeable so far as that can be done. A permanent removal from the hospital should be insisted upon as soon as it is safe to complete the convalescence at home or elsewhere, and an abundance of fresh air, indoors and out, should be supplied as the best curative agent from first to last. Arguing, moralizing, cheering up, rigid restraint, disciplining, sedative drugs simply for quieting patients, and still more bleeding and blistering, are for the most part things of the past. Mechanical restraint is all but abolished in the best hospitals, and is used only so far as it is considered the best medical treatment. A prison-like appearance of the wards has been found to be not only quite unnecessary, but harmful.

In many cases of insanity I make the question of removal to a large hospital one of circumstances and of money. If separation from the influences under which the disease occurs is necessary, and that cannot be secured at home, I usually select, as the case demands and opportunity is afforded, a private house with good nurses, a small private hospital, or an insane asylum where the general influences are the healthiest, where the medical treatment is in accordance with the best modern principles, and where the construction of the hospital is most nearly adapted to the requirements of the present day. Accessibility to visits of friends and the family physician where they help in the cure, and remoteness from them when they do harm, are also points to be considered. In many cases where the illness is of long duration a change of scene and association will prove of great service, even from one hospital to another. The permanent settling down into the routine of hospitalism is especially to be avoided. Of course there are cases, or rather conditions, in which a change would be detrimental to the last degree.

The associations, surroundings, and influences brought to bear upon the patient—what has been called the moral treatment—are of the first importance in the treatment of mental disease, and diet and hygiene come next. Medicines are of use in properly selected cases. The appetite must often be stimulated, the digestion regulated, and various painful symptoms must be relieved, so far as possible, without a resort to internal sedatives and narcotics. Rest and sleep are essential to recovery, but every effort should be made to obtain them by judicious regulation of outdoor exercise and of quiet as each case requires, abundant non-stimulating food frequently given, fresh air, tonics, baths, and removal of sources of irritation. Stimulants will sometimes be needed to prevent excessive exhaustion. Seclusion in a room darkened or not is useful in some conditions of excitement, and not seldom distressing symptoms are relieved by the simple presence of another person or by the absence of certain individuals.

Drugs of sufficient strength and in such quantity as to produce quiet or sleep should be used only when absolutely necessary, and then for as short a time as possible. Their prolonged use is open to many manifest objections in all persons, and particularly in those suffering from mental disorders, inasmuch as with them large doses, if any, are commonly given,

and it is very difficult often, in the impaired state of mind of the patient, to get indications of symptoms which contraindicate the use of a particular drug or to learn when it is producing harmful effects. Tonics are often indicated, but should be used with discrimination, as some of them, especially those affecting the cerebral circulation, frequently produce disagreeable results.

After apparent recovery there should be a long period of after-treatment, which in most cases will be best met in rest or travel.

In the various forms of mental disease, through concentration of the mind on various delusions and by excess or deficiency in mental activity, the ordinary symptoms of physical disturbance or disease, independent of the insanity, are so much modified as to be often overlooked. It goes without saying that intercurrent diseases and distressing symptoms should be treated on the principles generally applicable to those conditions, so far as that can be done without aggravating the insanity. The usual treatment of pneumonia, for instance, may in an insane person provoke such determined opposition or so excite or aggravate delusions that, so far as the disease of the lungs is concerned, it may be better to let it take its chance, with good general care, including food, warmth, etc.

The conditions of cerebral hyperæmia require cold applications to the head, the wet pack, prolonged warm baths, a non-stimulating diet, and quiet. If the condition is acute and of short duration, rest in bed is useful, provided it can be secured without force. For prolonged mental excitement from cerebral hyperæmia it will be usually better to equalize the circulation by that motor activity which is characteristic of the disease, and to allow free exercise in the open air, keeping within the limits of exhaustion. My experience has not justified the use of bleeding, except, possibly, in acute delirium (*mania peracuta*). It is difficult to limit the action of blisters, and they often irritate the patient so much as to do more harm than good. Persistent refusal of food is usually due to delirium or delusions, and should be met with a resort to feeding with the stomach-tube before the point of exhaustion is reached if the tact of a skilled nurse fails of success. Mechanical restraint increases the cerebral hyperæmia, and there are few homes or general hospitals where it must not be used if there is excessive violence or delirium, making the insane asylum in those cases a necessity. Objectionable as it is, however, mechanical restraint is less harmful than the continued use of large doses of sedative drugs, as is so often the practice, in order to keep patients quiet enough to remain at home.

Ergot, hydrate of chloral, and opiates, which sometimes must be given by the rectum or stomach-tube, are sometimes advisable for a short time, but must be used with great caution. Milder sedatives, especially the bromides, serve a temporary use in the less violent cases; but less sleep will often serve if secured by quiet, abundant liquid food, and general measures, and in exhaustion by alcoholic stimulants.

Menorrhagia is very common in the maniacal states. It usually requires no special treatment, unless so great as to produce exhaustion. Amenorrhœa is commonly conservative, and then demands only general treatment; if it causes evident disturbance of the cerebral circulation, the ordinary methods, including electricity, massage, and local use of leeches, should be used.

Galvanism is sometimes useful, applied to the head, in cases of mental torpor and stupor. That and the faradic current, used with great care, act as powerful tonics to the general nervous and muscular system.

Insomnia is often the chief manifestation of the insane taint, in which case drugs are, for the most part, worse than useless. In all forms of sleeplessness it is better to try malt, cod-liver oil, beer, food, massage, baths, exercise, rest, etc. before resorting to narcotics and sedatives. Camphor, hyoscyamus, cannabis indica, the valerianates, bromides, codeia are much less objectionable than chloral, morphine, and opium.

Where masturbation is simply an evidence of loss of self-control, it is met best by constant watching, and gradually, as the mental state improves, arranging the daily life so as to develop the feeling of self-respect. Where it depends upon local paræsthesia, opium and camphor and cold bathing are indicated.

Constipation is a troublesome symptom, especially in the states of mental depression. When a full, laxative diet, cod-liver oil, and malt do not correct it, small doses of laxatives given frequently act better than the occasional use of purgatives.

There is a class of cases which are best treated by educating the patients as one would educate a child.

In the general care of the insane it is the duty of the state to see that they have all the rights of the citizen which are consistent with their proper and safe treatment, including the benefits of property and estate. There certainly should be in all countries, as in England, officers whose duty it is to see that this is done. For a large number of people with defective or diseased brains, who are now allowed to wander about committing crimes and serving repeated sentences in reformatories, houses of correction, and prisons, an enlightened public policy would find the best, and in the end the cheapest, treatment to consist in keeping them under supervision and control as unsound members of society.

The more particular treatment of the insane differs in the various mental diseases, varying as it necessarily must according to different conditions. Its prevention is not an easy problem. Many of the external causes of insanity seem inevitable in our complex civilization: it would be impossible to widely regulate marriages, even if we knew how; those people predisposed to insanity are usually too self-confident and self-willed to receive advice; and moderation in all things, healthful occupation, temperate habits, good digestion, and, above all, out-of-door life, seem as much like a sarcasm if suggested to many of the toilers as a waste of words if recommended to the idle and luxurious, while the parents who have transmitted to their children unstable or diseased brains generally impair what chances they have in life by vicious training.

Where syphilis, drunkenness, and other marked sources of mental degeneration do not obtain, simple food, plenty of sleep, avoidance of extremes of heat and cold, plain dressing, baths, good digestion, out-of-door life, fresh air, careful attention to slight disorders or injuries of the brain and nervous system, guidance against too much study and too much excitement or dissipation, development of character and moral force, intellectual and physical training, avoidance of too much emotional, sentimental, or even artistic culture, careful watchfulness during the period of adolescence, occupation without overwork, healthful recreation, a con-

tented or philosophical mind, and suitable marriages, would produce the strong wills and healthy organisms needed to combat the tendencies of modern life. Such a course would undoubtedly make many a child with an hereditary predisposition to insanity become a healthy parent of children in whom the same treatment would soon eliminate the family taint. The character should be strengthened to learn to overcome difficulties rather than evade them. There are cases in which such a course can be adopted, and where the physician's advice may be of untold benefit to generations.

There are many crises in life when the mind totters and seems ready to fall, which the physician is more likely to recognize than any other person. Sometimes the odds are too heavy to fight against, but often there is a transient mental disturbance in such critical cases, or an incipient insanity, according as the indications are met with wisdom and patience or with neglect, indifference, and lack of judgment. The treatment called for is of the person rather than of the mental state, and in all forms of mental disease success in treatment depends very materially upon the personality of the physician, who must adapt himself also to the personality of the patient.

In about one-fourth of the cases of insanity there is no hereditary predisposition to the disease, and its prevention can be most hopefully looked for in attention to the general laws of health, the observance of which tends to secure immunity from all diseases. In the remaining cases—three times as many, in round numbers—the most hopeful course is in abstaining from marriage altogether or in the avoidance of unwise marriages; and it is an encouraging fact that many people in the community now take that conscientious view of the matter, although if they decide what to do without competent advice they are liable to err in the opposite direction of exaggerating their morbid tendencies, and so increasing their unhealthy predisposition. There are certain groups of physical and mental manifestations which the experienced physician recognizes as signs of tendencies which only await favorable conditions—a sufficient exciting cause—in the indulgence in drink or other excesses, in the exclusive search for wealth or fame, in the absence of healthy occupation, in mental wear and worry, in over-excitement, in the various conditions of ill-health, to develop into actual insanity. This physiognomy of temperament suggests to the observant physician a warning against excess of all kinds, and a recommendation for that course in life which promises the greatest likelihood of preserving a quiet mind and a healthy body and of securing a rational employment. Too much work is less dangerous to most people than too little.

States of Mental Defect and Degeneration.¹

MICROCEPHALISM, CRETINISM, INTELLECTUAL IDIOCY, MORAL IDIOCY, INTELLECTUAL IMBECILITY, MORAL IMBECILITY (under which Westphal, Spitzka, and others place moral insanity) are really names for different degrees of similar defects, for the most part hereditary and con-

¹ Compare Moreau's *La Psychologie morbide* and Morel's *Traité des Dégénérences physiques, intellectuelles; et morales de l'Espèce humaine*.

genital or resulting from disease or injury in infancy and early childhood, as distinguished from dementia, which is the result of later destructive mental or brain diseases. Idiots and the demented insane are sometimes so alike in their mental condition that, if young persons, they can be definitely distinguished one from the other only by a knowledge of the previous history of the case. Idiocy has its origin at or before birth or soon after, and terminal dementia seldom before puberty, commonly after maturity. In the United States census, where there is a doubt in the matter, the individual is classed as an idiot if the mental disorder occurred before the age of twelve in girls and fourteen in boys, and as insane (demented) if above that age.

The microcephalic brain may be as small as one-fifth the normal size, due chiefly to intra-uterine conditions for the most part unknown. Of course that means complete idiocy. The brains of other idiots differ in size and development. The mental condition in all is similar. Idiocy with the small or large or asymmetrical brain is classified, practically rather than scientifically, by Shuttleworth, as follows:

A. Congenital or Developmental¹ Cases.—1, Microcephalic, with small heads: forehead and occiput defective; 2, hydrocephalic; 3, plagiocephalic, with distorted heads: features in an oblique plane; 4, scaphocephalic, with keel-like distortion of forehead; 5, scrofulous cases; 6, Mongol type; 7, cretinoid cases, with stunted bodies: irregularly expanded heads and enlarged thyroid glands; 8, syphilitic cases; 9, primary neurotic, with body well developed: signs of irregular nervous action; 10, sensorial idiocy, with two or more senses deficient (*e. g.* sight and hearing); 11, mixed cases.

B. Non-Congenital, Acquired, or Accidental.—1, Traumatic; 2, post-febrile; 3, hydrocephalic; 4, hypertrophic, with large square-built heads; 5, eclampsic; 6, epileptic; 7, paralytic; 8, idiocy by deprivation: loss of two or more senses in infancy (*e. g.* sight and hearing); 9, emotional idiocy, with no bodily deformity: shrinking, scared expression; 10, toxic idiocy, with no bodily deformity: malnutrition.²

From the creature of deformed limbs and ape-like movements, incapable of articulate speech, even in monosyllables, or systematized ideas, leading a purely vegetative life, unclean, and with the instincts of a wild beast, up to moderate mental or moral imbecility, there are endless varieties of defects and monstrosities in mind, character, morals, and instincts, differing according to the profoundness of the disorder of the brain (hydrocephalus, atrophy, sclerosis, inflammation of the brain substance or membranes, injury from compression, blows, falls, convulsions, etc.), the extent of the defect in the brain development, the amount of the degenerative hereditary taint, or, in the case of cretinism, the importance of the endemic as well as the congenital influences.

In some of the higher planes of imbecility a considerable degree of intellectual brightness, or even talent, is often observed, and every variety of mental and moral perversion or simple reckless brutality. Training often does a great deal to bring many of these unfortunate creatures within the bounds of good behavior, but their care oftener falls within

¹ Developmental conveniently includes those cases which, though of intra-uterine origin, become more pronounced as physical development proceeds.

² "The Physical Features of Idiocy," *Liverpool Medico-Chirurgical Journal*, July, 1883.

the province of the medical superintendent in an asylum or the teacher than to the physician in general practice. They are easily led astray by others, and commit all sorts of motiveless crimes or with a trivial or disproportionate motive, and with blind disregard of consequences or inability to comprehend them. In the gallery, at Washington, of photographs of counterfeiters and of passers of counterfeit money, the faces of the latter show conclusively that they belong to the intellectually weak-minded or imbecile class. Their own amusement, gratification, or impulse is so far the basis of their conduct that only a minority are harmless if not more or less constantly watched. Fortunately, a great portion—unfortunately, not all—of the idiots are sterile, but many of the mentally and morally weak-minded, with striking congenital defects which no training can fully remedy, propagate their species indefinitely for the benefit of our prisons and asylums.

Intellectual idiocy and marked intellectual imbecility are so common as to constitute 1 in 650 of our population. Less noticeable intellectual imbecility is quite frequent in the large class of troublesome and perverse children and youth of both sexes, commonly called weak-minded.

Moral imbecility, which cannot be corrected by education, is less common.

Moral idiocy is rare. It consists in such an absence of the moral sense that it cannot be aroused. It is sometimes associated with sufficient intellectual powers to make deliberate action and premeditation quite possible. Such persons are monstrosities, who, for the safety of the community, must be kept shut up for life like wild beasts.

The fact should be remembered, from a medico-legal point of view, that the defective in mind are quite liable to short attacks of simple mania and mental depression and to epilepsy, both of the obvious type and of the obscure or masked form, so that their degrees of responsibility, or rather of irresponsibility, vary from time to time. As a rule, a good physical organization and a general condition denoting healthy circulation and nutrition mark the better brains, and constitute important elements in forming a prognosis in regard to the possibility of educating imbecile and feeble-minded children up to the point of reasonably good behavior and ability to at least partly take care of themselves. The simpler their lives and the more purely routine or imitative their work, the less their defect is noticed. Many can wheel a barrow as well as any one.

THE INSANE TEMPERAMENT (Insane Diathesis, *Neuro-psychopathische Constitution*) is an exaggeration of the nervous temperament. It is closely allied to insanity and the neuroses, and at the critical periods of life is very apt to develop into one of them. It is congenital or due to early interference with the normal development of the brain by injury or disease. It shows itself in childhood and infancy by irregular or disturbed sleep, irritability, apprehension, strange ideas, great sensitiveness to external impressions, high temperature, delirium, or convulsions from slight causes, disagreeable dreams and visions, romancing, intense feeling, periodic headache, muscular twitchings, capricious appetite, and great intolerance of stimulants and narcotics. At puberty developmental anomalies are often observed in girls, and not seldom perverted sexual instincts in both sexes. During adolescence there are often excessive shyness or bravado, always introspection and self-consciousness, and sometimes abeyance or absence of the sexual instinct, which, however,

is frequently of extraordinary intensity. The imitative and imaginative faculties may be quick. The affections and emotions are strong. Vehement dislikes are formed, and intense personal attachments result in extraordinary friendships, which not seldom swing suddenly around to bitter enmity or indifference. The natural home associations and feelings easily become disturbed or perverted. The passions are unduly a force in the character, which is commonly said to lack will-power. The individual's higher brain-centres are inhibited, and he dashes about like a ship without a rudder, fairly well if the winds are fair and the seas calm, but dependent upon the elements for the character and time of the final wreck. Invention, poetry, music, artistic taste, philanthropy, intensity, and originality are sometimes of a high order among these persons, but desultory, half-finished work and shiftlessness are much more common. With many of them concentrated, sustained effort is impossible, and attempts to keep them to it result disastrously. Their common sense, perception of the relations of life, executive or business faculty, and judgment are seldom well developed. The memory is now and then phenomenal. In later life there is a ready reaction to external circumstances, even to the weather, by which the individual is usually a little exhilarated or somewhat depressed. All sorts of vaso-motor disturbances are common and create distressing symptoms. Such people are said to be on the border-line between sanity and insanity. They are apt to be self-conscious, egoistic, suspicious, and morbidly conscientious; they easily become victims of insomnia, neurasthenic, hypochondriacal, neurotic, hysterical, or insane, and they offend against the proprieties of life or commit crimes with less cause or provocation than other persons. At the same time that many of them are among the most gifted and attractive people in their community, the majority are otherwise, and possess an uncommon capacity of making fools of themselves, being a nuisance to their friends and of little use to the world. Many of them get fairly well through life if their lives are tolerably easy or especially well regulated; if not, even they seldom escape further disturbance during the period of growing old. Their mortality-rate, especially from pulmonary consumption, is high. The prognosis is usually stated as unfavorable, largely, perhaps, because proper treatment is seldom pursued. If such children could be placed in the hands of judicious and experienced physicians from earliest years, much better results would undoubtedly be got and the downward tendency might be stopped. In the critical physiological periods of life, and under the influence of mental worry with physical strain, there is danger of breaking down. At the senile dissolution some of them lose much of their lifelong peculiarities, and as the mind fails in force and activity become more like other people. After the climacteric there may be also great improvement.

TREATMENT should consist in the general principles of mental hygiene, especially in training the mind to self-control and to avoid introspection—in a word, in maintaining health and in having healthy occupation. The earlier in life it begins, the better. It is well for such persons, unless of uncommon gifts in some direction, as many are, to obtain quiet, routine positions in life, and to avoid its wearing responsibilities as much as possible. The question of marriage is a difficult one for the physician if he is called upon for advice. Of course the risk often can be estimated only

approximately, even after knowing both parties, who will heed medical counsel implicitly if it happens to coincide with their own notions. The further propagation of the neuro-psychopathic constitution in the world involves much entirely uncompensated misery, as well as genius, enthusiasm, and originality, the compensation for which is estimated by society in one way as regards Burns, Byron, De Quincey, Carlyle, Goldsmith, John Howard, and Frederick the Great's father, and in another when considering the inmates of jails and almshouses and the destroyers of home peace. Maudsley thinks that one such poet as Shelley justifies the risks of marriage in the insane diathesis, and Savage considers the neuro-psychopathic constitution a useful element in society; while Clouston holds that the world would be better off to lose the few ill-balanced geniuses, the hundreds of impracticable, unwise talented men and women, and the thousands of people who cannot get on, shiftless, given to drink, idle, improvident, and unpractical, to get rid of the insane diathesis, especially if we shall find a middle course and learn to apply the laws of heredity so as to save the best and eliminate the unsound. It is to this class probably that Pinel refers in saying that what he calls moral insanity is largely a matter of bad education. It is undoubtedly true that judicious training in very many cases would limit, if not prevent, the further development of the morbid element and strengthen the healthy side, so as to prevent actual insanity.

CONSTITUTIONAL AFFECTIVE MENTAL DISEASE is a further development of the congenital or hereditary predisposition to nervous or mental disease, with more or less of the marks of the neuro-psychopathic constitution. It is of two forms, the depressed and the mildly exhilarated, in neither case amounting to simple melancholia or mild mania. Sometimes the two forms are seen in a single member or in different members of one family where mental degeneration has begun. The frequent association of pulmonary consumption with these cases is possibly, in part, due to malnutrition in those persons living under the influence of more or less perpetual gloom, and to exposure and over-exertion in those who are constantly unnaturally excited, sleeping too little and driving their alert brains to the extent of exhaustion. Misanthropists, communists, iconoclasts of all kinds, enthusiasts and reformers, useful people and worse than useless, common nuisances, criminals, saints, and heroes, are found among them. Undoubtedly, in the case of criminals the tyranny of their organization deprives the intellect of much of the proper inhibitory power over the passions and evil tendencies, and yet with sufficient motive they can hold themselves considerably in check.

The PROGNOSIS is not favorable. At the critical periods of life, after severe diseases or injuries and with undue mental or physical strain, there is danger of further progress of the disease into more pronounced types; and this result is often the only way of satisfying the community that what they called meanness or wickedness was only disease. The progress of the disease is commonly very slow. It often seems like simple progressive development of character, except for the fact, generally overlooked, that it advances often in a different direction to what would be natural, and is independent of normal development. The subsidence of habitual severe headache not seldom marks a sharp advance in the severity of the mental symptoms.

The TREATMENT is hygienic. It must begin early in life, and be devoted especially to avoidance of mental overwork, to healthy occupation, to simple habits, and to a wise mental training.

MORAL INSANITY (Insanity of Action, Affective Insanity, *l'Insanité morale*, *Moralisches Irresein*, *Folie raisonnante*, *Folie lucide*, *Manie sans délire* of Pinel), the general moral mania of Ray, is distinguished by that writer from partial moral mania (instinctive mania, *manie raisonnante* of Pinel, *la folie impulsive*, impulsive insanity, emotional insanity, *impulsives Irresein*), which includes suicidal insanity, homicidal insanity, dipsomania, pyromania, kleptomania, erotomania, nymphomania, satyriasis (*aidoiomania*), animal impulse, perverted sexual instinct (*conträre Sexualempfindung*, *la sensation sexuelle contraire*), and topophobia, if that disease be classed among the insanities.

Moral insanity is seldom seen in the insane asylum until the disease has passed over into pronounced mental enfeeblement or delusional insanity. Purely moral insanity—"an uncontrollable violence of the emotions and instincts"—is probably as rare as purely intellectual insanity. Moral insanity is attended with some mental impairment, just as moral perversion is part of intellectual insanity. Indeed, I have heard patients complain as much of the degradation of character in their insanity as of any symptoms referable directly to the intellect. The term is not a fortunate one, but, like the expression moral treatment of the insane, it is in quite general use. It is recognized by all the authorities on mental disease, whatever may be their opinions as to the limitations of responsibility in it. It is especially to it that we can apply the words of the Autocrat of the Breakfast-Table, that the worst forms of insanity are those to which the asylum shuts its doors. It is marked by moral perversion, change of character and action, and so little intellectual impairment as to be easily overlooked by one not familiar with morbid mental phenomena.

Mild simple mania ending in recovery has been described as moral insanity even by Pinel and Pritchard, and is so miscalled rather generally at the present day. Moral deterioration is observed after fevers or physiological periods of life, following slight and moderate cerebral hemorrhages or injuries to the back and head, affecting the brain, mental strain, etc., which, in persons of the neuro-psychopathic constitution, now and then end in permanent change of character. A similar but curable mental state is the frequent beginning of more pronounced insanity, and often remains the sole evidence of unsoundness of mind even after the patient is thought well enough to be discharged from the asylum.

Although moral insanity is probably a common cause of young persons of both sexes being led into lives of licentiousness, wickedness, and crime, it is to be carefully differentiated from deliberate yielding to temptation and following lives of vice until a strong enough motive is offered for doing better or a punishment is made sufficient to be deterrent.

Moral insanity is essentially a very slowly progressive and incurable disease, starting in congenital or acquired mental deterioration, and with its symptoms. It usually ends, after long years of wretchedness to the individual and misery to his friends, in more general insanity, slowly advancing dementia, death by intercurrent disease or accident, or in suicide. It is a most distressing disease in the young, who are punished

by parents and teachers in succession, sent about from one school to another, boarded with friends or with disciplinarians until all are wearied out in turn, and all too late conclude that the case is one for a doctor or perhaps an asylum. At the evolution of the sexual power and at its decadence, during menstruation, pregnancy, childbirth, lactation, especially after fevers, blows injuring the brain, and cerebral disease or disorders of any kind, are the periods of especial danger, as more general mental disease is then developed with seemingly trivial exciting causes. The friends observe that the sufferers do not seem entirely natural. They imagine and suspect a great deal, rather than possess real delusions. They often say that their heads are not quite right, and manifest an evidently diminished capacity for mental work, which tires them or makes them irritable. Modest girls become indelicate, the truthful lie, the delicate use profane and obscene language, the mild-mannered destroy furniture and clothing, the peaceful quarrel, the gentle storm and rave; and yet there is a standard of virtue and right, often a high one, on which they theorize, and up to which they often think that they live. They take strong dislikes to those with whom they are brought in contact, especially their nearest relatives. They often lose the capacity to do work, and now and then become spendthrifts or drunkards. As a rule, there are frequent periods of quiet, amounting to depression, but rarely reaching the condition of melancholia. Alternation or periodicity in the symptoms is the rule. After threatening and even endangering the lives of those nearest to them, insulting and indelicate conduct in public, perhaps frequent arrests, a dozen times outwitting those who wish to confine them in asylums, where they belong, their minds being alert enough to attribute their conduct to drink or some cause for which they receive slight punishment, and to argue their own cases so as to convince almost any jury of their sanity, the rule is that their doubts, imaginations, and suspicions deepen into active insane delusions, their mental impairment advances to noticeable dementia, their moral deterioration goes on to such a degree of depravity that every body wonders why they had not been seen to be insane long ago, and they are secluded in an asylum or elsewhere. A not uncommon but unfortunate end is when they kill themselves before anybody but a few specialists recognize their irresponsibility. Their recklessness and want of judgment are often the cause of fatal illnesses and accidents. Clouston reports the case of a lady who by a series of extraordinary misrepresentations and clever impostures raised large sums of money on no security whatever, and spent them as recklessly; imposed on jewellers, so that they trusted her with goods worth hundreds of pounds; furnished grand houses at the expense of trusting upholsterers; introduced herself by open impudence to one great nobleman after another, and then introduced her dupes, who, on the faith of these distinguished social connections, at once disgorged money. To one person she was a great literary character; to another of royal descent; to another she had immense expectations; to another she was a stern religionist. At last all this lying, cheating, scheming, and imposture developed into marked insanity and brain disease, of which she soon died; and it was seen that all these people had been the dupes of a lunatic whose very boldness, cunning, and mendacity had been the direct result of her insanity.

S. K. Towle has reported the case of a man whom he had under

his care at the Soldiers' Home near Milwaukee, Wis., as follows: "He had been a lieutenant in a volunteer regiment, and I gave him rather more privileges on that account, but after a time I found that he was more nearly an example of total depravity than I had ever seen. There was no truth in him, and he was intelligent enough to make his lies often seem plausible to me as well as to others. By his writing and talking and conduct generally he kept the patients and their friends in a ferment, and gave me more trouble than the whole hospital besides. He had a small scar about the middle of his forehead, which he said was due to a slight flesh wound from a glancing ball in battle. While he was under my care an older brother came to see him, and he told me that up to the time his brother, my patient, who so tried my patience, entered the army he was almost a model young man, amiable and affectionate, the pet of the whole family and intimate friends; 'But,' said he, 'ever since he came back he has been possessed of a devil if ever any one was.' After a time, much to my delight, he asked for a transfer to the Soldiers' Home at Dayton, Ohio, which I got for him with commendable alacrity; and he went there. His conduct at Dayton was the same as with me, but after a few months he quite suddenly died, when an autopsy was made. In sawing open the skull, at the point of the small scar on his forehead the saw came directly upon the butt end of a conical bullet, two-thirds of which projected through the skull, piercing the membranes and into the brain. The internal table of the skull had been considerably splintered by the ball, the pieces not being entirely separated, and there was evidence of severe chronic inflammation all around, and quite a collection of pus in the brain where the ball projected into it. Here was the devil that had possessed the poor fellow—that not only took his life, but destroyed his character, lost him the love and esteem of his friends, and doomed him for half a dozen years to do things he would most have hated and despised when he was himself. Dunlap, the assistant surgeon at Dayton, told me that he found in this man's trunk letters from several—half a dozen, I think, at least—women in various places, from which it appeared that he was engaged to be married to each one of them. The letters were neatly tied up in packages, each one's separately, in several instances with photographs supposed to be of the writers, and the date of reception and reply was noted on many of the letters in a business-like way."

As Westphal well says¹ of such persons, "They often think correctly and logically, and show reflection and deliberation to a certain degree; but there is a certain something lacking, and there are some general conceptions, general processes of thought and judgment, of which they are incapable. Their mentality stops short on a certain plane, especially in matters of judgment where every even uneducated person easily succeeds. They sometimes act as if they had good judgment and common sense, of which they are really destitute, particularly in regard to the proprieties of life and their proper social relations and duties. Certain of the finer feelings are absolutely impossible of development in them. Through their various acts, perverted by their mental defect, the patients often seem perverse (*bösartig*), passionate (*leidenschaftlich*), although of true sustained passion they are incapable. What seems passion is a sudden idea or fitful impulse to which they yield at once. Moral insanity is a defect in the affective

¹ *Berl. klin. Wochenschrift*, 1878, No. 15.

sphere, but also an intellectual defect of a peculiar kind, which is often concealed under the mask of a perverted moral sense, and which requires time and practice on the part of the physician for its detection."

Moral insanity is quite certain to pursue a downward course, although something can be done by training, general hygiene, simple diet, mental discipline, avoiding overwork, a judicious choice of the few occupations of which the moral insane are capable, and a constant steadying hand to help them try to keep their balance.

IMPULSIVE INSANITY is perhaps more properly called instinctive monomania, as the morbid impulse is usually shown in only one insane propensity at a time. Like moral insanity, its manifestations are commonly periodic, or at least alternating. Under the name of emotional insanity it furnishes sympathetic juries with an excuse for finding not guilty of murder women who kill their betrayers and husbands who shoot a wife's seducer. It is a not uncommon symptom in a considerable proportion of the persons suffering from the various forms of insanity. As a separate disease it is quite rare, and includes those persons whose insanity is manifested, as Marc says, by what they do rather than by what they say. The insane impulse does not come from any logical process. It is rarely provoked by or associated with a criminal motive, except in an analogous way to the production by excitement of an epileptic attack, to which, indeed, it offers some points of similarity. There would be reason to doubt the existence of the disease unless other indications of mental degeneration were present, especially where there is proof of a criminal motive or where the criminal act and the prisoner's statements are the sole evidence of unsoundness of mind. Unconsciousness, even temporary, and loss of memory, are not symptoms of instinctive monomania. On the contrary, the mind is quite clear, and resists successfully the insane impulse so long that the person affected with it has often gained confidence that he will never yield to it; and he soon learns the fact that, there being in circumstances external to himself no reason for the crime suggested to the mind with such force, temptations do not occur to the act. While the impulse lasts a great variety of distressing mental symptoms accompany it, so intense that the impulse often cannot be resisted, and then the terrible brain-tension is relieved. I doubt whether hallucinations of hearing are found in impulsive insanity, and incline to think that all the reported cases where crimes of impulse have been committed in obedience to a voice commanding the individual to do this or that act of violence are more properly classified under other forms of mental disease. One kind of instinctive monomania sometimes disappears to be replaced by another. In developing boys and girls there is not seldom a pathological mental state during which lying, stealing, running away from home, etc. are common for several months or a few years; but this is a curable condition, and does not by any means necessarily end in instinctive monomania.

Suicidal insanity is probably the most common form of instinctive monomania. The force, or even presence, of the suicidal impulse is largely dependent upon the general tone of the system. The suicidal idea is common; it occurs to the minds of a vast number of sane people at one time or another under adverse circumstances. Hysterical women talk a lot of nonsense on the subject. Self-destruction due to self-depreci-

ation, weariness of life, and general gloom is not uncommon in the insane temperament. It is also a refuge to proud and sensitive people who have sacrificed their honor. But this is quite different from suicidal insanity, in which the impulse is often strongest at a time when there are the most reasons for living and the greatest happiness in life if the tormenting demon urging to self-murder could be excluded. Such people finally kill themselves, in spite of their best resolutions and efforts to the contrary, if the various faculties of the mind become more and more involved as the disease goes on and the power of self-control is progressively weakened. More general insanity of the degenerative type is sometimes developed from suicidal insanity.

Homicidal insanity is fortunately still rarer than the last-mentioned form, although motiveless homicidal ideas occur to husbands and wives and parents with reference to those dearest to them, under conditions of prolonged mental strain or exhaustion, during pregnancy and the puerperal state, and at the climacterium. In suspected crimes the evidence of homicidal insanity should be clear and should rest upon the general signs of the degenerative mental state. Homicidal impulses are common enough among the insane. Just as there are persons who do not dare to have sharp instruments in their rooms for fear of killing themselves, so there are others to whose minds axes, knives, and razors suggest imperative conceptions of plans for killing another. It is difficult in either case for the physician to satisfy himself at what point real insanity begins. Seclusion under the morbid influences of an asylum is very bad treatment for the individual, and symptoms which seem very serious often disappear by restoring the general health. In a recent case,¹ where a youth of nineteen was acquitted of the murder of his mother on the ground of homicidal insanity, he knew that the act was wrong, realized that he had committed a crime, and was full of grief for it, as occurs in all such cases. It is the rule, too, that there is some condition of mental defect or degeneration out of which the homicidal insanity is developed.

Dipsomania, a rare manifestation of impulsive insanity, differs entirely from the acquired alcohol habit, drunkenness, acute or chronic alcoholism, delirium tremens, or habitual intoxication, all of which conditions are also more readily developed in the neuro-psychopathic constitution than in persons with healthy brains, and may reach a point constituting insanity. Dipsomania is periodic, uncontrollable, and associated with other evidences of the insane diathesis. The prognosis is unfavorable. The treatment is to improve the general nervous tone and to seclude the patient during his attacks.

Pyromania and kleptomania are not rare as symptoms of insanity of the marked forms which are observed in asylums. As manifestations of impulsive insanity—that is, as constituting a form of insanity—they are associated with other evidences of mental defect or degeneration. Burning and stealing alone are not indications of insanity. As such, they are without sane motive, and directed to objects in burning or stealing which there is no gain to the person and usually no gratification except the sense of relief which comes from yielding to the impulse, and of distressing mental symptoms if the impulse is resisted.

Nymphomania in the female, satyriasis in the male, and the various

¹ *Quarterly Journal of Mental Science*, October, 1883, p. 387.

perverse and degrading methods of gratification of the sexual instinct, may, when joined with other evidences of mental or nervous disorder, constitute one form of impulsive insanity. Erotomania, an ideal attachment without erotic feeling, is a more common mental disease, but the other evidences of insane conduct are quite striking. The same statement holds true of the many perverted instincts which, according to circumstances, are or are not manifestations of the defective brain-inhibition of disease. Animal impulse as a form of impulsive insanity I had been inclined to doubt until I recently saw two cases of as extreme mental suffering as I ever witnessed, in two refined ladies who had suffered also from some cerebral symptoms, occasional dizziness, and suicidal insanity, but who had no other symptoms of cerebral disorder than those which are grouped under the head of insane diathesis, and they not marked. It is not associated with any erotic feeling or with particular persons. There is more rapid wasting in flesh and strength and loss of sleep than in the other forms of impulsive insanity, and, in my experience, greater dread of yielding to the demon of unrest.

The perverted sexual instinct, with a feeling of repugnance to the opposite sex, has thus far been observed chiefly in persons who have been addicted to masturbation. It is marked by a passion for some individual of the same sex, by other evidences of the neuropathic condition, and commonly by a grotesque imitation of the habits or dress of the opposite sex.

The indications for treatment in impulsive insanity are cod-liver oil, the bromides, simple non-stimulating diet, open-air life, judiciously regulated exercise, mental occupation so far as is possible, and removal from suggestive surroundings and associations. The prognosis is not favorable as to the final result. If the symptoms disappear on restoration of the general health, other marked indications of cerebro-mental disorder are pretty certain to appear sooner or later.

HYSTERICAL INSANITY is one of the states of mental degeneration, much less common among men than among women, arising from the further development of a neurosis, hysteria, and probably to a great extent due to bad training. Hysterical symptoms, quite marked, are very common among young persons and in single women of all ages in simple mania. They are not uncommon in simple melancholia and in other forms of mental disease. They add somewhat to the gravity of the prognosis in these cases. They constitute a group of symptoms which I suppose to be understood by those authors who speak of hysterical insanity as a disease in which the cure-rate is high. But hysterical insanity, as quite distinct from other psychoses, is quite a different matter. It is characterized by extreme and rapid mobility of the mental symptoms—amnesia, exhilaration, melancholic depression, theatrical display, suspicion, distrust, prejudice, a curious combination of truth and more or less unconscious deception, with periods of mental clearness and sound judgment which are often of greater degree than is common in their families; sleeplessness, distressing and grotesque hallucinations of sight, distortion and perversion of facts rather than definite delusions, visions, hyperæsthesias, anæsthesias, paræsthesias, exceeding sensitiveness to light, touch, and sound, morbid attachments, fanciful beliefs, an unhealthy imagination, abortive or sensational suicidal manœuvres, occasional outbursts of violence, a curious combination of unspeakable wretch-

edness alternating with joy, generosity, and selfishness—of gifts and graces on the one hand and exactions on the other. The mental instability is like a vane veered by every zephyr. The most trifling causes start a mental whirlwind. There is no disease giving rise to more genuine suffering or appealing more strongly for the sympathy which, freely given, only does harm. One such person in the house wears out and outlives one after another every healthy member of the family who is unwisely allowed to devote herself with conscientious zeal to the invalid.

The PROGNOSIS is unfavorable. While the symptoms may be alleviated and a nominal cure may be effected, a relapse or the development of some other troublesome form of insanity or neurosis is the rule, to which the exceptions occur for the most part in women in whom there is also some serious curable uterine disease or a state of excessive physical prostration which can be relieved.

The TREATMENT of hysterical insanity demands tact and educating power which will tax to the utmost the ingenuity of the wisest physician. Sympathetic friends, and sympathy in general, are useful in moderation, but they oftener do great harm, because they are excessive; and the care which does good is that which, while being kind and firm, tends to develop strength and character. The will and the imagination are so extraordinarily powerful that their wise direction and government constitute the most important part of successful treatment. Diversion, occupation, and the development of self-control, with careful attention to the general laws of health, are quite important. The temptation to use drugs is, like the fascination of being pitied and petted, very great, as alcohol, chloral, or opium often acts like magic for the time being, and there is generally a craving for one or all of them. But they are utterly demoralizing in the end. The habitual use of stimulants and narcotics in such cases only increases the evil. The fact must be recognized that the hysterical insane are often least responsible where they seem most so, and that they must be treated with unending patience, kindness, gentle firmness, and a wise ignoring of most of the symptoms. Simple palliative sedatives which cannot do harm must sometimes be used, but the general rule, the less active treatment the better, is safest. In the few cases where benefit has been got from removal of the ovaries, healthy or diseased, the improvement, if it shall prove to be lasting, will probably be attributable to the great physiological shock from the operation rather than to any relation of the ovaries to the disease. Removal from home is usually advisable for a time at least—often it is necessary; and if residence in an asylum is not thought to be wise, properly-selected hydropathic establishments or private asylums are useful. Living in a judicious physician's home is desirable when a suitable one can be found. In an asylum a rational letting-alone treatment is found to be the most successful. If the patient remains at home, hired nurses should be in charge of the patient, or at least not members of the family. Safe seclusion will be found necessary for the few who will not otherwise be prevented from committing crimes and offences of startling ingenuity or conspicuous publicity.

EPILEPTIC INSANITY arises from a neurosis, epilepsy, which almost inevitably ends in mental deterioration of greater or less degree, from scarcely noticeable impairment to complete dementia. The insanity may

be a continuous state; it may be subsequent to the epileptic attack, or precede it, or take the place of it. Epileptic dementia is more nearly allied to idiocy than dementia following other mental diseases, and it is associated with a degree of moral perversion and brutality which is quite uncommon in other dementia. The insanity following or preceding the epileptic attack is attended with stupor, delusions of persecution, confusion, transitory fury, or a condition quite analogous to somnambulism or cerebral automatism; and the same may be said of insanity replacing the epileptic attack, except that the most common condition in it is a violent maniacal fury, with unconsciousness, and subsequent nearly if not quite complete amnesia. The forms of mental impairment are progressive in the vast majority of cases. The other forms are more amenable to the usual treatment of epilepsy, and sometimes diminish in severity as the disease advances and the mind becomes weakened. In the fury which takes the place of the epileptic convulsion there is in nearly every case—I am inclined to think in all cases—an intellectual aura, a slight change of action, observable early enough to give warning of the approaching storm, which can always be mitigated, and often entirely prevented, by absolute rest in bed and the use of chloral and the bromides.

Although some few epileptics become well without treatment, and a small number permanently recover under treatment, the PROGNOSIS is even less favorable for the epileptic insane. The care of insane epileptics should embrace, in the first place, safety to the community by secluding those dangerous to it, and, second, the usual hygienic and medical treatment of epilepsy.

Epileptic vertigo, analogous to *petit mal*, is a transitory mania, often associated with passing delusions.

With regard to the responsibility of the epileptic insane—and, indeed, all epileptics—the facts should be borne in mind that their mental state is usually one of such instability that a slight irritation of any kind is apt to induce a full or modified convulsion, and that under provocation they commit partly volitional crimes, for which they are not fully responsible.

HYPOCHONDRIACAL INSANITY differs only in degree from hypochondriasis, described on a subsequent page. It is an incurable manifestation of one type of the mental degenerations. It is slowly progressive, and often ends in dementia. It differs from hypochondriacal melancholia in being an evolution of mental defect or degeneration, and in the fact that the mental depression, which is usually of a mild, periodic, or impulsive form, is secondary to the other symptoms, and not, as in hypochondriacal melancholia, the mental condition out of which the hypochondriacal symptoms are evolved.

The TREATMENT consists in attention to the general laws of health, occupation, and a fattening diet. It is seldom successfully managed without occasional recourse to an asylum at least, and oftenest a permanent residence in hospitals, occasionally changing, is quite necessary.

PERIODIC INSANITY, usually mania or melancholia, is marked by attacks recurring at more or less regular intervals, with a partial but not complete return to the previous mental health between them. It is one of the incurable degenerative mental diseases. The seeming recovery is only apparent, and the mental deterioration is progressive, although quite slow. The form of insanity is also not seldom a *folie raisonnante* (affective

or moral insanity) with periods of all sorts of excesses, destructive tendencies, tramp-life, destructive acts, drunkenness, stealing, indecent exposure, etc. In the intervals, which may be short or long, and which sometimes correspond to certain seasons of the year, the mental condition is still a pathological one, with the usual signs of mental degeneration, thereby being differentiated from recurrent insanity, one of the curable psychoneuroses, in which there is a state of mental health between the successive attacks, but no sort of regularity or periodicity in the recurrences. The prognosis is unfavorable, except in so far as a quiet life in an asylum tends to prolong the intervals between the periodic outbreaks, as well as to prevent annoyance to the community during them.

CIRCULAR INSANITY (Alternating insanity, Folie circulaire, Folie à double forme, Folie à formes alternes, Die cyclische Psychose, Das circulaire Irresein) consists in a psycho-rhythm or succession, in uniform order in each particular case, of (1) mental exaltation in all degrees, from mild exhilaration or even gayness to acute mania, and (2) mental depression of all conditions, torpor, or anergic stupor. These two opposite mental conditions are separated in the vast majority of cases by a shorter or longer interval of the normal mental state, in which, however, there is soon observed some mental impairment, however slight, rarely amounting to pronounced dementia except in old age. Sometimes the three states shade off into each other, so that it is difficult to say just where one begins and the other ends; less often the transition is abrupt, sometimes during sleep. The interval between the two opposite conditions of mind may succeed either of the other mental stages, but the order once established is maintained. The duration of the vicious circle varies in succeeding attacks, sometimes becoming longer, sometimes shorter, in the progress of the disease. The relative duration of the three succeeding mental condition also varies, but the type of each remains identical, or at least changes very gradually. The state of mental exaltation often resembles moral insanity, with all sorts of immoral impulses and tendencies, and may then properly be called an insanity of action. The depression sometimes goes no farther than sluggishness of will. The tendency of the disease is to shorten life only slightly, if at all, except from the chance of suicide in the depressed state and from exhaustion when the excited stage is one of active mania. The shortest duration of the cycle in my experience has been twenty-four hours, and the longest reported extends over several years. It sometimes remains an affective insanity in its whole course, without delusions and with little more dementia than might happen from simply a corresponding advance in age without mental disease.

During the period of excitement some supervision or control will usually be desirable, and removal to some retreat or asylum will often be necessary. In the depressed stage the indications are to maintain the general health, to meet the chances of suicide, and if there are delusions to obviate the risks of danger to other persons. If the interval of comparative mental health is of considerable duration, the ordinary occupation of the patient can commonly be followed at that time for a number of years, rarely for life; but a better result may be looked for if the patient's circumstances are such that he can give up active and anxious work for some quiet occupation not involving great care.

PRIMARY INSANITY (primäre Verrücktheit, primordiale Verrücktheit,

originäre Verrücktheit) is usually a further development of an hereditary predisposition to mental disease. The term primary monomania, although used as an equivalent for primäre Verrücktheit, seems to me too narrow for a disease in which the leading delusion may change so many times. Primary insanity is sometimes congenital, and may be developed also by injury or by disease involving the brain early in life or during the physiological changes at puberty, possibly by self-abuse, in persons of an unstable mental organization. It often develops so slowly with the character as to almost seem part of it, until it reaches such a degree of insane delusion of self-importance and expansive ideas as to be unmistakable insanity. There are also delusions of persecution, distrust, and suspicion, erotomania, and moral perversion, in spite of high claims to superior character, and indeed in spite of a high standard of life in some particulars. Perhaps the most striking symptom of primary insanity is the great variety of imperative conceptions (*Zwangsvorstellungen*) by virtue of which the individual is impelled, by a force often irresistible, to commit various offences against propriety and the laws, even to murder, as well as to perform countless acts of un wisdom or folly. There are usually physical indications of chronic or old cerebral disease, or of defect or degeneration in the incomplete or asymmetrical development of the brain, which, however, may be no more than are found in persons who might not be classed as of unsound mind. Attacks of simple mania (mental excitement) of short duration are quite common, and there is a progressive impairment of the higher faculties of the brain—those which come last in a high order of civilization—although there may be acuteness of memory, perspicacity, and shrewdness which seem altogether phenomenal as compared with the other mental qualities. There is no form of mental disease which is better expressed by the word craziness than primary insanity, no other in which the victim is more thoroughly in the grasp of his malady, and yet no other in which he is more likely to be held responsible for the crazy acts which he may perform, because his inherent mental state, out of which his generally deluded frame of mind is evolved, gives rise to delusive ideas of such a character that they are not universally recognized, even by physicians of experience in mental disease, as insane delusions, but are considered by some of them as the prevarications of a criminally-minded person. When these persons commit crimes, too, they often do so with methods and motives quite like those of the ordinary criminal.

The PROGNOSIS in primary insanity, after the disease is fully developed, is in the highest degree unfavorable. It remains to be seen how much can be done by moral training in childhood and youth to correct the evil tendency. The education of those who get into the courts and insane asylums, so far as my knowledge of such cases goes, has been bad to the last degree, so that, in my opinion, there has been a fair difference of opinion as to which of them the law should treat as criminals and which as insane persons.

TREATMENT for the most part requires absolute control of the individual, which there is usually no one in the family sound enough to maintain. If begun early, training away from home may accomplish much. Restraint in some institution is commonly called for, but the vast majority of the primary insane are allowed to take their chances in

the world, and as many end in jails and prisons or on the scaffold as in asylums.

The states of mental defect and degeneration, except in the case of idiocy or marked imbecility, are not associated with such obvious physical evidences of deviation from a normal mental standard as to make them pathognomonic. While asymmetry and other cerebral defects are frequently observed in them, it must be acknowledged with Schüle that similar and as extensive gross intracranial anomalies are found in persons who could not be called of unsound mind, and that this statement holds true even of primary insanity, in which some writers have laid so much stress upon the value of any indication of imperfect or asymmetrical cerebral development. Any defect in the brain, however, is far more common among persons of unsound mind than among those of sound mind, and therefore in doubtful cases it is of a certain value as corroborative evidence of mental infirmity or impairment.

Spitzka places as signs of the insane constitution (1) atypical asymmetry of the cerebral hemispheres as regards bulk; (2) atypical asymmetry in the gyral development; (3) persistence of embryonic features in the gyral arrangement; (4) defective development of the great interhemispheric commissure; (5) irregular and defective development of the great ganglia and of the conducting tracts; (6) anomalies in the development of the minute elements of the brain; (7) abnormal arrangement of the cerebral vascular channels,—at the same time acknowledging that there are cases of insanity of inherited origin in which cerebral defects are not discernible. It is too early to estimate the value and importance of the finer or qualitative cerebral defects as giving rise to insanity. Benedikt finds them also in criminals.

With regard to responsibility before the law, the statutes of no country provide for any criterion by which accountability is defined in these cases; medical witnesses differ in opinion as to their criminality, and the courts are obliged to interpret the law to suit individual cases.

The states of mental defect and degeneration are not sharply defined. They run more or less into one another. The fact should also be kept in mind that isolated symptoms and groups of symptoms belonging to them are repeatedly found in curable conditions of physical and mental exhaustion in neurotic persons.

The degenerative mental states are thought to be increasing, to furnish material for the increase in the otherwise curable insanities, and to thus include much of that portion of the community which is most filling up our institutions with incurable cases. It is probably in the prevention of them, or at least in the proper training and disposition of children affected with them or predisposed to them, that the most can be done to stay the increase of insanity. Perhaps at some time unwise marriages of passion and sentiment will be less common than now, and the rights of children to a fair start in life more considered.

Psychoneuroses.

AFFECTIVE MENTAL DISEASE is a *folie raisonnante*, one of the reasoning insanities, sometimes called moral insanity, and very like the moral

insanity already described, except in the absence of signs of mental degeneration and in the fact that it is a curable disorder. It is an insanity of action, marked by scarcely noticeable mental impairment. It often is the early stage of more serious mental disease, and not seldom its symptoms remain, as simply change of character, after the striking symptoms of extensive mental disorder have disappeared. It also exists and is cured without the appearance of more pronounced insanity. At the time of the climacteric it is a form of mental disorder not uncommon among women, who, however, usually fail to recognize it as such until they have recovered. Maudsley includes under this head simple melancholia, simple mania, and moral alienation, but it will be more convenient for the present purpose to use the term affective mental disease as indicating a curable moral alienation or change of character affecting the intellect chiefly so far as the judgment and sense of propriety only are concerned, and not dependent upon constitutional defect or developed degenerative mental state. There is usually slight exhilaration or depression, which alternates or varies from time to time.

The PROGNOSIS is favorable.

The TREATMENT is brain-nutrition, with those general measures already described.

HYPOCHONDRIASIS, as Flint¹ well says, belongs in the list of disorders of the mind, although the mental alienation is not regarded as amounting to insanity. The mental state is one of morbid imagination and apprehension rather than of definite delusion, and it consists in a belief in the existence, present or to come, of maladies and diseased conditions for which there is no foundation in fact, in spite of sufficient proof of their unreality. There is usually, not always, mental depression. Its causes lie in conditions, usually obscure, which lower the tone of the general health, including hereditary weaknesses, or depress the vitality of the brain either by physical wear or mental worry, and the exhausting influence of functional disorders or of organic diseases which may not be discovered before the autopsy. Disappointment, bad habits, want of proper mental occupation are often at fault.

The physical symptoms of hypochondriasis are commonly those associated with impaired digestion and nutrition—namely, anæmia, dyspepsia, neurasthenia, constipation, flatulence, headache or a feeling of discomfort after using the brain, less appetite, slight loss of flesh, disordered sleep.

The mental indications are more or less melancholy, indisposition to exertion, irritability, diminished power of self-control, and an inability to cease except temporarily from interpreting signs, proved to be trivial, as indicating grave maladies or as forewarnings of severe disease to come. Sometimes the fixed idea is limited to a single false conception, but oftener slight changes in physical symptoms or differing phases of morbid introspection produce a complete kaleidoscope of pictures of fancied misery. The whole catalogue of diseases, or a large part of it, may be exhausted, with the help of some of the many foolish treatises always ready for hypochondriacs or from reading medical books and talking with charlatans, who are consulted at rapid intervals, one after another, both by those who wander from office to office and those who take to their beds. The most common type of hypochondriasis arises, directly or indirectly,

¹ *Practice of Medicine*, p. 854.

in some form of unhealthy or false ideas regarding the sexual function, and in the idea that some imagined or exaggerated abuse of it has produced or will produce most serious evils; but there is not an organ of the body which may not be the basis for the unwholesome thoughts. Not seldom there is simply the delusion of especial weakness or sensitiveness or delicacy.

Hypochondriasis may be only the early stage of more serious mental disease. It may be one manifestation of an hereditary neurosis or psychoneurosis, or it may arise from deterioration of the body's vitality by organic disease, especially of the abdominal or pelvic organs or through some incurable weakness or functional disorder. In either of these cases its cause and duration will be determined by the clinical history. As an uncomplicated psychoneurosis hypochondria lasts from a few months to a number of years, with very little change in its prominent symptoms, resulting in recovery for the most part, becoming chronic in a moderate proportion of cases, and rarely proving fatal except by some accidental complication, including suicide.

The PATHOLOGY AND MORBID ANATOMY of the disease are unknown.

The differential DIAGNOSIS consists in the exclusion of other diseases.

The PROGNOSIS is favorable in uncomplicated cases.

TREATMENT consists in measures to improve the general health, especially a full diet carefully selected, hydro-therapeutics, massage, gymnastics, horseback riding, walking, rowing, abundant and agreeable exercise in the open air, and the management of the patient's surroundings so as to lighten the mind and relieve from worry, perhaps by travel, sea-voyages, etc. Argument is commonly worse than useless, but there should be a decided impression given that the generally morbid state is due to ill-health. The risk of suicide is so small that restrictions of liberty directed to its prevention do more harm than good. It goes without saying that bad habits should be reformed, narcotics should be avoided, and a healthy occupation should be encouraged, or, if possible, insisted upon. The difficulties in treatment are fully as great with the highly-educated superstitious and credulous people whom we find in the literary and professional circles as in the ignorant and weak-minded.

MELANCHOLIA (*Die Melancholie*, *Schwermuth*, *Tiefsinn*, *Trübsinn*, *Lypemanie*, *Mélancolie*, *Aliénation partielle depressive*, *Monomanie triste*, *Phrenalgie*, *Psychalgia*) is one of the functional mental diseases, in the sense that the pathological condition of the brain upon which it depends is not yet known, although it is thought to begin with disturbances in circulation and nutrition, which end, if not resulting in cure, in atrophic, degenerative, and inflammatory states, indicating, in the great majority of cases, extensive brain disease. As a rule, melancholia first appears in a slight change of character; the patient is said by his friends to be not quite like himself. After some days or months, as the case may be, the symptoms develop into settled gloom associated with mental pain—the state known as

Simple Melancholia (*Mélancolie raisonnée*), in which the events of life are correctly observed, but, incorrectly interpreted, are the source of constant apprehension, self-depreciation, depression, and despondency. There are no delusions, properly speaking, and yet there is a disposition to take the dark-side view even of circumstances which promise favor-

ably, which amounts to a generally deluded state of mind. Commonly there is increased irritability, now and then a genuine moral insanity, and occasionally in neuropathic constitutions the state of mind already described under the head of Impulsive Insanity, of which the suicidal impulse is the least infrequent. Sometimes there are no physical indications of disease, but as a rule there are headache, increased sensibility to light and noise, sleeplessness, restlessness, impaired appetite and digestion, gastro-intestinal catarrh, marked loss of flesh, diminished or abolished sexual desire, and in women usually delayed menstruation or amenorrhœa. A few persons are able to keep up, in an irregular sort of way, their customary employment. In the majority of cases it is impossible to concentrate the mind upon work, mental occupation fatigues the brain, and the physical strength is too impaired for steady labor. Suicide is thought of probably in nearly every case, as it is by many sane people at some time in their lives, but it is very seldom committed unless there are such disgraceful or distressing acts performed or suffered by them as would tempt to suicide in sane people. There is no danger of deliberate homicidal acts in persons of good character. A criminally disposed person would more readily commit murder in simple melancholia than if free from that disease.

Simple melancholia may be the initial stage of almost all of the mental diseases, especially acute mania, paralytic dementia, and the severer forms of melancholia. It may be differentiated from the first stage of mania only by waiting until other symptoms appear or not, and the same is true with regard to distinguishing it from the forms of melancholia involving danger to life. In the latter case, however, there is much greater difficulty in diagnosis, inasmuch as insane delusions may be concealed, and there may be so slight a change in the patient's behavior when delusions appear in his mind that the closest observation is needed to guard against them. The simple melancholia marking the first stage of paralytic dementia is characterized by noticeable although often slight mental impairment—a distinctly diminished capacity for work, of which the individual himself is not seldom conscious, whereas in the disease simple melancholia the mind's usual power is exerted, provided its attention can be withdrawn from morbid introspection and concentrated upon any subject, as it commonly can be for a while.

Melancholia with delusions (acute melancholia) is commonly a further development of simple melancholia, but sometimes its course is so rapid that if there is a period of mental depression without delusion it is overlooked. The earliest and most common delusion is some form of causeless self-reproach with regard to some matter, whether trivial or important, or of groundless self-accusation, of impossible sins of omission or commission, but generally of some vague, undefinable fault, as having irretrievably offended God or committed the unpardonable sin, etc. Often this and an unfounded belief in self-unworthiness are the only delusions present, and in that case within narrowed limitations the mind acts soundly in other matters. The feeling of personal fault or sin often expands to a sense of the justice of punishment, and the consequent delusion that all sorts of terrible things are to happen—poverty, the poorhouse, or some great unknown dread, even involving family and friends; and from personal sin or fault it is only a step to the belief

that the world is all wrong, and to the certainty that everything is going to worse than ruin. Illusions of sight and hearing may magnify common fires and locomotive whistles into general conflagrations of the world and shrieks of tormented persons. Hallucinations of the special senses may create visions of all sorts of imaginary horrors, sounds of voices saying every possible dreadful thing, odors most disagreeable, tastes most vile. Anæsthesia prompts the delusion of death, and hyperæsthesia of burning, freezing, scalding, etc. Some mysterious force within them, which they can neither explain nor understand, drives them to automatic acts of all kinds—to obscenity, profanity, verbigeration, intonation of sentences, wailing, screaming, destructiveness, etc. In cases of exceptional severity the mind seems deluded on almost every subject: the food is poisoned, the atmosphere is deadly, the world loses all its reality, friends their identity, things their substance. They are to be burned alive, starved, quartered, suffocated, smothered, drowned. Every conceivable and inconceivable thing is to happen. The delusions are nearly always of the illogical or unsystematized kind, although systematized delusions of persecution are met, for the most part, in incurable cases. Deliberate plans of suicide are formed in most cases, and are to be suspected in all. Homicidal attempts are apt to be made upon persons whom it is desired to save from impending calamities. Suicidal, and less often homicidal, impulses occur. Suicide and homicide from deliberation need, to be successful, (1) the opportunity, (2) lack of power of self-control, and (3) a strong determination. Sometimes there is the will without the opportunity, or the opportunity with self-control; and for this reason persons in danger of killing themselves or others often for months escape any acts of violence. Not seldom, too, they determine to kill themselves or family in a particular way, and neglect other chances so long that they are thought to be not meditating destruction of self or others. When the determination or impulse to suicide or homicide is persistent and desperate, no means are too horrible and no opportunities too hopeless to be attempted. There is no reason for a special name for these symptoms, but they have been called suicidal melancholia and homicidal melancholia. No more is there any justification of the term hypochondriacal melancholia for melancholia with hypochondriacal symptoms.

In melancholia with delusions there is sooner or later, in the majority of cases, refusal to eat, from lack of appetite, nausea, or disgust of food, from disagreeable hallucinations of taste or smell, from delusions that it is a sin to eat, that the stomach is full, that the mouth is sealed or the throat obstructed, that the food is not and cannot be paid for, that eating will do no good, etc., from a wish to commit suicide by starving, or in the states of stupor (*attonitäts-zustände*) from mental torpor or stupidity. Sometimes there is resistance to the calls to eat, urinate, or defecate by virtue of resistive melancholia—a condition to resist and oppose everything—or from delusions that it will destroy the soul, etc. to follow the natural inclinations. Refusal of food may be under certain conditions instinctive and conservative. It is the exception for the bodily functions to be well performed. Usually, there is obstinate constipation, with headache, coated tongue, greater variation in daily temperature than is usual in health, accelerated pulse, and rapid wasting in flesh. The various anomalous sensations observed in functional diseases of the nervous

system are common. Masturbation is a not infrequent symptom of loss of self-control in both sexes.

Acute melancholia is sometimes confounded with delusional insanity with mental depression. In the former the delusions are evolved from the mental state; in the latter, the mental state from the delusions. In the former the delusions are for the most part unsystematized: the patient cannot state why he believes them to be true; in the latter there is correct reasoning from false premises: the delusions are logical or systematized and of a depressing character, so that a belief in them naturally gives rise to sadness.

Before the courts the fact should be kept in mind that persons with acute melancholia have diminished power of self-control by virtue of their disease, and so yield more readily to temptation than in health. They also may have imperative conceptions—ideas so strong that they cannot, or can with difficulty, resist carrying them out even when they know them to be wrong; and there may be sudden outbursts of almost maniacal excitement. They are often able to make wills and perform contracts, in form and in detail, as well as ever, when they are so filled with insane delusions as to be on the point of killing themselves and their families. There is impaired capacity, however, of recognizing the relations of persons and things to one another, a distinct moral perversion, and a diminished recognition of obligations and sense of responsibility. In other words, they are not always fully themselves on those points in which they seem to be so, and yet patients in asylums with acute melancholia have been known to give the best of advice to their business-partners.

Melancholia with stupor (*melancholia attonita*) appears like complete dementia or a mindless state, but there are now and then evidences of intelligence. The mind is filled with overwhelming and terrible delusions, which paralyze the will and place mental and physical activity for a while in abeyance. It arises commonly in the course of the less profound form of melancholia, after some great mental shock, and there is a condition of marked anæmia of the brain, probably symptomatic rather than pathognomonic, which if not soon relieved goes on rapidly to atrophy and degeneration. Except when there are attacks of frenzy, which may occur at any time, there is little danger of active violent acts except suicide, desperate refusal of food, and determined resistance to any care or treatment. There are the usual indications of physical exhaustion.

In melancholia *agitata* the mind is clear and active, the opposite of the condition last described, and the distressing delusions produce such a degree of motor excitement arising from the mental suffering that the disease closely simulates acute mania. The mind not only reacts as readily as in health to distressing ideas, but abandons itself more fully to their domination through diminished will-power and lack of self-control. Almost blind acts of desperation and fury are committed from which the utmost vigilance can hardly save them.

The three severe forms of melancholia just described are interchangeable in the same person during the course of his illness, so that the states of frenzy and stupor are more properly called symptoms than classes of disease.

Melancholia among children is more common than the books state it to be, although rarely met in the asylums. Magnan has reported a

suicidal case in a child four years old, and it occurs up to the latest years of life.

The DURATION of simple melancholia is from a few weeks to a dozen years; of acute melancholia, from a month to two or three years, after which it is apt to end in chronicity; melancholia stupida (with stupor) is usually curable, if at all, in the first year, although relapses are frequent, and in melancholia agitata from a year to three years is the common limit of the possibility of a cure.

The PROGNOSIS in simple melancholia is favorable. Including cases treated out of asylums, probably 90 per cent. recover; in acute melancholia, uncomplicated with other diseases, not far from two-thirds recover; in melancholia attonita less than half get well; and in melancholia agitata nominal recovery occurs perhaps in a third of the cases, although I doubt whether complete restoration to health is seen often.

In chronic melancholia the process of mental deterioration is slow. As the mind becomes impaired the delusions lose their activity and the mind reacts less readily, so that a state of less suffering and greater calm is reached, and the patients are often useful workers in asylums for many years, or remain in their own homes a constant source of anxiety to those who understand their condition. Many of them commit suicide.

In treatment of melancholia the first indication is to protect society and the individual against acts of violence. Homicidal acts are not to be feared in simple melancholia, unless in persons of bad character and ugly temper, or in those few cases with the symptoms, in addition, of moral insanity or impulsive insanity. Suicide is so rare that precautions will not often be needed against it, provided the patient is so frank or so transparent that the appearance of distinct delusions may be detected and then guarded against. In cases of long standing, especially in persons beyond middle age, this is extremely difficult, and their treatment outside of asylums must always be attended with risk. In the other forms of melancholia the fact should be taken for granted that the patient is suicidal, and he may be also homicidal, so that he should be watched constantly and efficiently, and never left alone or with weak or helpless persons, no matter how free from suicidal determination or impulse he may have appeared. The puerperal mother, especially, is a source of the greatest danger to her child, even when she seems natural and fond. The degree and kind of watching varies, according to the severity of the case, from the constant presence or close proximity of some responsible person, who may sleep in the same room with the usual home-surroundings, to the most vigilant and wakeful personal care every moment day and night, and removal of every source of possible self-injury. In some few cases this can be well done only in an asylum or in a padded room. Some form of restraint, either personal or by confining or limiting the movements of the hands in rare cases of exceptional desperation, will be found necessary.

Placing the patient in an entirely healthy atmosphere is next in importance. In the very earliest stage quiet, recreation, change of scene, and association with a pleasant and judicious companion are often sufficient to effect a cure. If the disease is pronounced, rest and removal from sources of irritation are more important until convalescence, when travel may be tried. The question of removal from home and commitment to an asylum

should be decided upon the grounds already stated in considering the general treatment of mental diseases. The degree in which the patient should have exercise, occupation, and recreation or be let alone will be determined for each individual case. The fact should be borne in mind that the disease is a debilitating one, and that it arises in conditions of mental or physical exhaustion. Massage and a modified rest-cure, without seclusion, are beneficial in some cases, especially of elderly people. Baths and the cold pack should be used with discrimination. Electricity, where it does not give rise or add to delusions, is a useful tonic, especially in passive cases. There are very few patients of such desperate frenzy as to require confinement of the hands, and that should only be done with an attendant close at hand. Whatever is done, nothing should be attempted which excites delusions unless it be absolutely necessary. Fresh air, and an abundance of it, are very important. Experience and careful study of the particular case will be needed to know how far to press the taking of food. But the necessary amount should be given by the stomach-tube if ordinary means fail, and it is better to use it early rather than tire the patient out with ineffectual attempts with spoons, etc. Whether the nasal or œsophageal tube be used—of which I prefer the latter—the greatest care should be taken not to inject food into the lungs, the throat being so devoid of sensitiveness sometimes that the tube may be passed into the trachea. Nutrient enemata may be relied upon for a week or two if the patient is in bed, but no longer.

Tonics are indicated—cod-liver oil with bark, the hypophosphites, dilute phosphoric acid, malt. Strychnia, iron, and quinine should be used with caution, as they often cause disagreeable headache with indisposition to sleep. Fattening food will be found useful in most cases. The few fat melancholics need nitrogenous food and graduated exercise. Constipation will be corrected in many cases by a full, laxative diet, cod-liver oil, malt, or it may be beer. Mineral water or Sprudel salts are usually indicated. A pill containing aloin, strychnia, belladonna, mastich, or even colocynth or podophyllin, may be needed in obstinate constipation.

Medicines to control restlessness and sleeplessness should be avoided if possible. Hydrate of chloral, opium, bromides, valerian, sometimes increase the difficulty, and the objections to their prolonged use are obvious, and yet they must sometimes be used for a time. The bromides, with cannabis indica, valerianate of zinc, camphor, and hyoseyamus, may serve an excellent purpose for a time. Opium and its preparations, where they agree, act like magic in producing mental calm and sleep. They may relieve constipation and increase the desire for food, but the danger of the opium habit is so great that their use should be decided upon only in extreme cases, and the effect should be watched from dose to dose, each one of which should be given under medical direction. Wilful masturbation, one of the signs of loss of self-control which occurs in the best of people, cannot be corrected by drugs or appliances, but only by constant watching and by placing the individual where his self-respect, as soon as it can be appealed to, will keep him from it. If it is uncontrollable and symptomatic, fresh air and exercise, and, if necessary, bromides or opiates in moderate doses, with a tonic (not iron), should be used.

MANIA (Manie, Exaltation générale), according to Morel, meant, in the original Greek, folie or madness, while Esquirol derives it from the Greek word meaning moon, making the words maniac and lunatic equivalent. The word mania is still used in this loose way, even by writers on mental disease, as a synonym of insanity. Its use is properly restricted to conditions of mental exhilaration or excitement with motor activity. The morbid anatomy of the disease is not yet made out, and the indications of hyperæmia observed in the acute stage after death are no greater than are found in diseases in which mania is not a symptom. In its final stages atrophic, degenerative, and inflammatory signs are abundant and well marked.

Simple mania¹ (manie sans délire, manie raisonnante), an exaltation of the mental faculties similar to the exhilaration produced by too much wine, with an accelerated flow of ideas, impaired judgment, and motor activity, without definite delusions, delirium, or incoherence, has been called an insanity of action, affective insanity, folie raisonnante, and even moral insanity, from which it differs in being marked by constant mental elation and exaltation of the physical functions, and not necessarily by striking moral perversion. It is a mental erethism, an exaggerated gayety, an uncontrollable exhilaration, an unbounded joy, an excessive anxiety, a perpetual anger, unusually good spirits, increased intellectual and physical energy, with such striking loss of self-control, diminished powers of reflection, and so decided weakening of the judgment that all sorts of unwonted errors of commission or omission may be performed. Under its influence many fortunes have been lost, many reputations have been ruined, and the happiness of many families has been sacrificed before the existence of insanity was suspected, except possibly by a very few persons. Indeed, the wit is usually so sharpened, the flow of ideas often so clear and rapid, the capacity for brain- and body-work without fatigue is generally so increased, that not seldom the patient is remarked upon as being unusually well. The most troublesome symptoms arise from the tendency to squander property, to drink alcoholic liquors to excess, and, especially in women, to allow the exalted sexual desires to get control of the judgment and reason, thereby bringing about unfortunate marriages or scandalous relations with the opposite sex. In women there is commonly increased menstrual flow.

The course of the disease is without material change, and the duration is from several weeks to a number of years. When it does not constitute the initial stage of other types of mental disease, especially severer forms of mania, circular insanity, general paralysis, or (in the neuropathic constitutions and at the critical ages) mental degeneration, the termination is in recovery in about 90 per cent. of the cases, although sometimes some moral impairment or deterioration in character remains for life. The recklessness incident to the disease leads to unusual risks, now and then to fatal accidents. Simple mania rarely becomes chronic.

TREATMENT involves the necessity of proper control to prevent scandals, disasters, and perhaps crimes. The matter of the degree of seclusion and control should be governed by the general considerations already mentioned in the general treatment of insanity, bearing in mind that

¹ Also called by some writers moral insanity, folie morale, folie des actes, folie or manie instinctive.

repression of the motor energy, except to prevent exhaustion, does harm. The demand for food is enormous; its supply should be abundant and judiciously chosen with reference to easy digestion. Frequent prolonged warm baths and cool applications to the head are indicated, and the usual palliatives for headache, sleeplessness, constipation, etc. The surroundings should be such as to favor rest and undisturbed sleep, and to dispel sources of excitement, whether they arise in certain associations, localities, occupations, or persons.

Acute mania (*Tobsucht*) follows an incubative stage of simple melancholia, often of simple mania, and rarely bursts out without previous indications of disease. Delusions, unsystematized and illogical, are abundant; the ideas flow so rapidly that the mechanism of speech is not adequate to their expression; the motor excitement is intense. In the most severe forms there is mental confusion, delirium, incoherence of ideas, and furious muscular action, to the point often of acts of destructiveness and self-injury. The clothing is torn to shreds, and no act of violence is too wild not to be attempted without warning. The skin is hot, the tongue heavily coated, the pulse accelerated, the temperature elevated, more, probably, than would be accounted for by the physical activity—from one to two or three degrees—now and then, in conditions of exhaustion, a little below the normal. Just as there is liable to be maniacal frenzy in the course of severe melancholia, so in acute mania outbursts are seen of desperately suicidal melancholic frenzy. Unless great care is used to keep up the strength, and often in spite of it, exhaustion rapidly sets in, under the influence of which the symptoms are very much aggravated. The amenorrhœa in women in this condition is conservative.

The COURSE AND DURATION of acute mania vary within wide limits, with an average of not far from six months, with recoveries in about 60 per cent. of first cases uncomplicated by pneumonia, chronic disease, or a marked neuropathic state: 5 or 6 per cent. die, chiefly from pneumonia, phthisis, accidents, or exhaustion, seldom suicide. Incurable cases drop slowly into dementia or into chronic delusional insanity, the motor excitement subsiding. The delusional insanity may be simply a stage in the process toward dementia.

In the DIAGNOSIS of acute mania, unless great care is used, the physician sometimes finds that he has sent to the asylum a case of acute, especially infectious disease, in the early stage and with unusual manifestations of febrile delirium. The indications for avoiding this unfortunate mistake are care and time in making diagnoses.

In the TREATMENT of acute mania the matter of foremost importance is that the physician should be able to sufficiently control his patient to prevent harm, and that he should have him in such a place as to give him an abundance of fresh air, unhampered by annoying and irritating limitations of his free will, restrictions of his liberty, and repression of his motor excitement. The risks of injury to others must be reasonably provided against. It goes without saying that few homes meet these indications: very few people can command a house to be converted into a virtual hospital, with the care of trained physicians to direct every little detail of treatment, and proper nursing. The public asylum, therefore, or the private retreat must usually be depended upon. In the case

of quiet young people, especially of young women whose illness may be of such a nature as to justify their marrying after recovery, and in the acute mania following childbirth, it is well worth the physician's while to make an effort to keep the patient in a private house when the conditions are such as to make such a course practicable. To the rest and quiet which may be had under such circumstances, with all the goings on of the house regulated to the patient's comfort and convenience, to prolonged hot baths, a full simple diet, given with the stomach-tube if necessary, as few medicines as can be got on with, the supervision of the nurses by some judicious member of the family, and the gentleness (combined, of course, with proper firmness) of home-influences, I attach very great importance in properly selected cases. But I attribute as much to the restful influence of keeping the patients among familiar scenes, and where some familiar face and voice can reassure them in their comparatively clear moments, instead of their being agitated and distressed to know how to account for the strange people and cell-like room of the insane ward to which they will awaken from their delirium in the hospital. It is something to avoid the excitement of commitment and removal to an asylum, with all that they involve, as well as the sight of demented patients, whose noise may make sleep impossible just when it is most needed. Acute mania seems to me to arise much less often than other mental diseases in definite associations which need to be escaped from for successful treatment.

The term subacute mania is used by some writers for the milder cases of acute mania, just as acute delirious mania is a term which is applied to those violent cases of acute mania in which furious and prolonged delirium marks the disease, and in which there is a high death-rate and low proportion of recoveries.

In chronic mania the motor excitement, mental instability, and, sooner or later, delusions, if not present at the beginning, as is usual, continue. The progress to dementia is commonly slow, and there are few cases which it is wise to treat away from an asylum or its dependencies on account of the possible danger to others from sudden exacerbations of the disease or through uncontrolled violent impulses.

Although there is no pathological condition distinctive of mania in its curable stage, conditions indicating hyperemia are usually found, whether as a result of the disease or its underlying cause, and sometimes meningitis. In chronic mania there is in the terminal stages evidence of atrophic and degenerative changes which do not distinguish it from other forms of mental disease.

ACUTE DELIRIUM is the typhomania of Bell. Its prevailing mental state is of mania oftener than of melancholia. It resembles the worst cases of typhoid fever so closely, and it is so uncommon a form of disease, that the mistake has often been made of sending typhoid-fever patients to insane asylums. The mistake is unnecessary, as the clinical features of typhoid fever are so well marked that with sufficient care and delay they may be recognized if the physician does not commit the common error in mania of being too much afraid of his patient to examine him thoroughly. The tendency to exhaustion in acute delirium is rarely successfully combated, as the motor excitement is so intense and the delirium so furious that nourishment to meet the tremendous demands of the

system can seldom be given, and death is the usual result. Recoveries are rare, but less uncommon in the melancholic than in the maniacal form.

Little need be said in the way of TREATMENT, except that in so speedily fatal a disease it is well to keep the patient at home, if he can be properly cared for there.

TRANSITORY INSANITY is used by Krafft-Ebing¹ (*Transitorisches Irresein*) as indicating mental disease differing from other insanity only in the fact that it is of short duration—namely, from two to six days. If it is applied to sudden and transient outbursts of mania, with delirium, loss of power of self-control, and inability to clearly recollect the circumstances of the attack and what happened during its continuance, it is a rare disease, occurring for the most part in epileptics and in persons under the influence of alcohol or addicted to its habitual use. It is sometimes, under the latter-named condition, called alcoholic trance. It consists in an automatic state resembling the epileptic delirium, which may occur also in sleep and resemble somnambulism. The actions are guided by co-ordinated will without conscious intelligence, and may consist in crimes and brutalities and foolishness entirely inconsistent with the character in health. It seldom lasts more than a few hours. When caused by alcohol or as a symptom of epilepsy, it may occur without other marked inciting cause; otherwise it is commonly due to mental shock. Several cases happened during the mental excitement of the first battle in our civil war. The most striking case within my own experience was that of a man who under the strain of prolonged grief and the mental shock of a great fire destroying a large part of the town in which he lived, perhaps moderately affected by alcohol, suddenly grasped an axe and cut off with one blow the head of a beloved child. He was found in the street without knowing how he had got there or what he had done.

One attack is the rule, although several, probably of an epileptic nature, have been reported. It is an extremely difficult condition to diagnosticate with certainty, and is therefore often the refuge of criminals and a resource of criminal lawyers. The most likely honest mistake liable to be made regarding it is to confound it with an outburst of passion.

PRIMARY DEMENTIA (Acute dementia, Stuporous insanity, Anergic stupor) is a disease chiefly of youth and early maturity in persons of inherited weakness or under the influence of prolonged exhausting conditions, to which some mental shock usually adds the immediate cause. Although most of the cases are under the age of twenty-five, it occurs up to forty-five. Masturbation is so common a symptom in its course—and it may be one of the debilitating and enervating factors constituting a predisposing cause—that most of the primary dementia is classed in some asylums as insanity of masturbation. There may be an initial stage of a number of days, marked by moderate melancholia or by maniacal excitement, but there is usually mental torpor advancing rapidly to pronounced dementia. In rare cases there is marked chorea, and slight choreic movements are often observed. The course of primary dementia may be subacute and advance with extreme slowness.

There is no overwhelming delusion paralyzing the mind, so to speak, as in melancholia attonita (melancholia with stupor). In acute cases the brain quickly falls into a state of profound anæmia, precisely such as is

¹ *Irrenfreund*, 1883, p. 113.

found post-mortem in starved dogs, and loses its power to a greater or less extent of reacting to the stimulus of the senses. There is little or no sensation of hunger, the sensory nerves are nearly or quite paralyzed, the bladder and rectum become distended until urine and feces are voided unconsciously or at least uncontrolled, and voluntary movements almost cease, although the muscles are capable of acting if directed: if led or pushed, the patient walks; if placed in a chair or bed, remains there; and in the worst cases lies on the floor quite inattentive to all the decencies of life unless constantly looked after. There is always partial, and there may be complete, anæsthesia, to such an extent that even the involuntary muscles do not respond to the ordinary stimuli. There is rapid loss of flesh, very sluggish circulation, and feeble heart-action. After recovery the patient speaks of the stage of his greatest illness as a blank in his memory.

This description of pronounced cases of primary dementia of the most severe type needs modification as applied to milder cases, which may exist in all degrees, down to a state of mental impairment of very moderate extent.

The mental impairment may be progressive and quite incurable, but also so slight in the beginning, and may make such slow progress, as to entirely escape detection for several years, and then attract attention at first by the lowered plane of character and loss of self-control in little matters of daily life, rather than by the intellectual deterioration, which by that time has become quite marked. This subacute form of primary dementia in young people rarely finds its way into the insane asylum until the second, third, or fourth year of its course, and then its progress is slowly downward. It has none of the eccentric or grotesque features of hebephrenia, and little of its emotional disturbances.

Subacute primary dementia in the later years of maturity, just before or several years before the climacteric, is of grave import, as it indicates the development of an hereditary predisposition to insanity in a form which not only offers no reasonable hope of recovery, but also is quite certain to manifest a change of character which is even more difficult to treat and properly control than the intellectual failure. As it is most likely to arise under circumstances of wear and worry, its symptoms may be for a long time attributed to disappointment or bad temper. After the dementia becomes pronounced its downward course is seldom otherwise than very rapid.

SECONDARY DEMENTIA is a convenient name for the curable dementia which appears at the subsidence of acute symptoms occasionally in mania, and rarely in melancholia—that is, just about the beginning of the period of convalescence. It is also called secondary stupor.

In primary and secondary dementia, resulting in recovery, the progress of the disease is rarely otherwise than very rapid, and unless a cure takes place in a few months at the outside, secondary changes occur in the brain and the tendency is to terminal or incurable dementia. So many cases are treated outside of asylums that it is difficult to estimate the cure-rate, but it is probably not less than 60 or 70 per cent., although it is quite common in the apparent cures for the brain to remain on a lower intellectual or moral plane than if the disease had not occurred.

TREATMENT does not involve the necessity of removal from home in

the acute cases, except when that is demanded for convenience of treatment. There is no melancholia to suggest the possibility of suicide, and no mental exhilaration or motor excitement to make restraint necessary. The most important indications are met by abundant, easily-assimilated food, which must usually, for a time at least, be given with a spoon or by the stomach-tube; fresh air, attention to the processes of digestion, relief of the gastro-intestinal catarrh by the usual remedies, stimulating baths, tonics, stimulants, and general galvanism. Proper care in emptying the bladder and rectum and entire cleanliness will suggest themselves.

In mild cases a tonic and stimulating regimen, including sea-bathing and gymnastics, will often be sufficient.

In the subacute cases young people are easily depressed by the asylum associations, but there is usually a time in the progress of the disease when home-discipline is too weak for them, and they must be sent away; older people have usually complications in their home-life such as to make a change desirable for the comfort of the household. Recoveries are extremely exceptional.

In all cases there is little to be gained in keeping up home-associations for so disturbing, distressing a disease after there is pronounced dementia.

Medicines, other than tonics, are of little use, except opiates to control various distressing nervous symptoms, including masturbation, but they should be used with great caution.

KATATONIA (*Katatonie* of Kahlbaum; *Katatonische Verrücktheit* of Schüle) presents, with more or less regularity of appearance, symptoms of (1) mild melancholia without the characteristic mental pain; (2) mental excitation, sometimes ecstatic, with cataleptiform conditions; (3) confusion and torpor or apathy. There is an underlying well-marked intellectual impairment, slowly advancing in incurable cases to pronounced dementia. Delusions, more of the unsystematized than of the systematized character, but resembling both, constitute a prominent part of the disease from the beginning. Verbigeration and a curious sort of pomposity are usually found in more or less pronounced degree. The delusions are mixed. They are exalted, hypochondriacal, melancholic, with all sorts of self-accusation, and may be full of suspicion, fears of poisoning, and ideas of persecution. Hallucinations of the special senses and illusions are not uncommon. If the term *katatonia* is not used, or at least if a special place in the nosology were not given this disease, it would be difficult to know whether to class these cases as primary dementia, melancholia with delusions, delusional insanity, or confusional insanity.

The verbigeration, when it exists, and the expression of delusions are often associated with a manner on the part of the patient suggesting disbelief in them, and sometimes the patient smiles or laughs at the astonishing character of his statements. There is a self-conscious element at times, suggesting mimicry or hysteria; a certain pathos is universal; opposition and contradiction, even to refusal to eat, leave the bed, dress, wash, are quite common; and nurse and physician are tired out with the monotony of the mental and physical state. Well-marked catalepsy is not common in my experience, although it occurs; and in all cases I have seen the mental state and physical atony suggesting that condition. Little attention has as yet been given to *katatonia* in asylums in this country. Judging from my own experience, it is not a common disease.

Its CAUSES apparently lie in prolonged mental exhaustion and inattention to bodily health. I have been led to suspect syphilis as at least a predisposing cause.

The COURSE AND DURATION of katatonia are tedious, and even if there is apparent recovery from the first attack, the tendency is to relapses and to slowly-advancing dementia and death from those causes of which demented in hospitals die, especially phthisis. I have never seen a complete and permanent recovery.

The MORBID ANATOMY of katatonia suggests a deep-seated neurosis, the precise nature of which we do not understand. In terminal stages there are atrophy and degeneration and all that goes with them.

The CLINICAL HISTORY of katatonia is so characteristic that it need be confused with the other diseases already mentioned as simulating features of it, and with the early stage of general paralysis, only through insufficient observation or too hasty diagnosis.

It is difficult to treat katatonia without the conveniences of a hospital.

PRIMARY CONFUSIONAL INSANITY is a term recently introduced for a form of mental disease of which the most marked features are moderate fever rapidly developed, confusion, incoherence, and mild delirium. The onset of the disease is rapid. In some of the cases which I have seen the diagnosis was made of typhoid fever, although the clinical marks of that disease were absent, the general appearance of the patient in the two diseases being quite similar.

There is no real melancholia or exaltation, no rapid flow of ideas, and no dementia. Hallucinations of the special senses are common; there is a consciousness of illness; the delusions are unsystematized, and the confusion of ideas frequently goes to the point of not being able to recognize persons and places. The usual signs of fever are present for a few days, but the temperature rarely exceeds 102° F., and soon drops to nearly or quite the normal.

The COURSE of the disease is quite rapid, and if recovery does not take place in several weeks or a few months, chronic insanity with delusions or dementia of various degrees may be expected.

The MORBID ANATOMY is not distinctive of this condition in the early stage, and we cannot yet differentiate it from simple fevers by the post-mortem. If ending in incurability, the atrophic and degenerative changes of chronic mental disease are found.

As regards removal from home, the considerations already referred to should be the guide. It is a good rule to keep the patient at home if a suitable one for the purpose, and to resort to the asylum in case of chronicity or troublesome complications.

PRIMARY DELUSIONAL INSANITY (*Folie systematisée*, *Verrücktheit*¹) differs from secondary delusional insanity in the facts that the disease arises primarily, and not secondarily to other mental diseases; that there is little or no mental enfeeblement in the early stage; and that the delusions, although fixed and systematized, are limited. It has the advantage of allowing the avoidance of the misleading terms *monomanie* of the French and *monomania* of English and American writers, the narrower forms of which may be included under the term primary insanity (*primäre Ver-*

¹ Called also by some writers *Wahnsinn*, although they use the term for secondary delusional insanity also.

rücktheit), including the further developments of the neuropathic constitution, especially those with the physical marks of degeneration described by Sander as originäre Verrücktheit, and those marked by imperative conceptions and such delusions of self-importance, suspicion, etc. as seem to some people evidence of insanity, while by others they are considered as simply false beliefs not indicating mental disease. Unlike primary insanity, which is one of the states of mental defect and degeneration, and incurable, primary delusional insanity may occur in persons of healthy mental organization, and may end in recovery,¹ although it is one of the most distinctly hereditary forms of insanity, generally speaking.

There are several subdivisions of primary delusional insanity, according to the character of the delusions: (1) with delusions of unseen agency, suspicion, and persecution; (2) with delusions of personal exaltation; (3) with delusions transformed from sensations.

Delusions of unseen agency, suspicion, and persecution appear either acutely and expand very rapidly in a few weeks, or from a very insidious beginning so gradually that they may exist for months or years before they are detected. The general indications of illness consist in impaired sleep, slight loss of flesh, some reserve or shyness in relations with other people, and diminished ability to concentrate the mind in the usual occupations. The mental impairment at first is very slight, and shows itself (1) in the readiness with which the absurd delusions are believed and the fixedness of their hold on the mind, and (2) in the diminished general power of judgment and self-control in the little matters of daily life, at first so slight that it is not seen except in matters requiring some effort to maintain the customary equilibrium. Hallucinations, especially of hearing, appear. In the progress of the disease the mind loses power of self-control more and more, the delusions become more fixed, concealment is no longer possible, and the patient is so annoyed or angered that he repeatedly seeks relief from the courts (*Querulantenwahnsinn*) or commits some act of violence in self-defence. The common delusions are of marital infidelity, attempts at poisoning, mesmerism, electricity, influence through telegraphs, telephones, poisoned air, etc., signs of which are evolved directly from the consciousness or transformed from common sights and sounds, such as ringing of bells, striking of clocks, simple ordinary motions, etc. The delusions in time produce a state of mental depression.

In some cases the primary delusion is of personal exaltation, attended with persecution and mental depression. The individual thinks himself some great personage unjustly deprived of his rights.

Delusions of grandeur or of personal exaltation develop in the same way, usually subacutely from what might seem a foolish fancy rather than an insane belief. The Napoleons, kings, queens, greatest financiers, gods, etc. of the insane asylums are those who reason correctly if one concedes the truth of their false premises, until the progress of the disease produces such general brain-enfeeblement that their premises and their

¹ Some writers include both diseases under the term monomania, and make both incurable degenerative states, which is contrary to my experience. Clouston also has seen cures in what he calls monomania (primary delusional insanity) without the neuropathic taint.

reasoning from them are both insane. The delusions lose their fixedness, and their force too, in the general lowering of the mind's strength, and complaints and boasts and acts of anger become fewer, and finally cease.

The COURSE of the disease is nearly always subacute in the beginning and chronic to the end in the two forms of primary delusional insanity—that is, with (1) delusions of persecution and mental depression, and (2) delusions of grandeur. A few cases with acute development result in recovery, most of which relapse. The course is for the most part to chronic delusional insanity attended with moderate dementia.

The MORBID ANATOMY is not known, except that atrophic and degenerative changes—not distinctive, however—are found in the terminal stages.

The patient is rarely willing to be treated as an ill person, for he is sure of the correctness of his delusions. If during the first attack he can be entirely removed from his daily associations by change of scene and travel, or, if that is not possible, by admission or commitment to an asylum, before the delusions become fixed and while it is still safe for him to be at large, there is reasonable chance of recovery. Second or third attacks very seldom end in recovery unless they arise from alcoholic excess, when entire abstinence for a sufficient length of time affords fair hope of a favorable result, except in cases of long-standing drunkenness.

TREATMENT, when the delusions have become fixed, involves, chiefly, safety to society or its comfort. The patients rarely commit suicide, driven to desperation by their delusions of persecution when they are particularly horrible. The more common tendency is to acts of violence toward others, so that seclusion in an asylum is usually the only safe course to pursue for delusions which one week may be directed against certain persons who can easily be gotten out of the way, the next week may be directed against others, and so on indefinitely. Delusions of grandeur may be only a nuisance or annoyance, but may at any time become sources of danger. The course is, for the most part, to slowly-advancing dementia. Asylum treatment offers no chances of recovery in cases not depending upon alcoholic excess, but becomes necessary for the protection of society.

Transformed delusions (*sensorielle Verrücktheit*) arise usually in some anomaly of sensation, which probably directs the delusions already forming in a mind in the early stage of disease rather than causes the disease. The causes lie in a deep-seated exhaustion of the nervous system, especially in the neuropathic constitution and profound hysteria. Various anomalous sensations give rise to a belief in delusions as to their being caused by individuals for a purpose, or to their being an indication of all sorts of impossible and most extraordinary changes in the part: the chest is of stone, the leg of brass, the head on fire, the hand ice, and so on indefinitely. Hallucinations and a cataleptiform state are common. The variety of delusions which may arise is almost endless, and they may have their origin in the unhealthy action of any organ in the body: one of the most troublesome forms, called ovarian insanity by Skac, causes single women of severely continent lives to imagine all sorts of impossible marital relations with men whose lives are equally beyond scandal and above suspicion.

Without proper care the COURSE of the disease is to slowly-advancing

dementia; and this may be expected when there is organic disease of any important organ of the body.

Before the delusions are fixed, diversion, change of scene, travel under agreeable circumstances and judiciously regulated, may be of great benefit. In the later stage of firmly-fixed delusion asylum treatment offers more chances of success.

In all the forms of primary delusional insanity the whole history of the case is difficult to get at, and there may be, and usually is, so strong a tinge of possibility at least, if not of actual probability, in the delusions, in the early stage of the disease, that a correct diagnosis cannot be arrived at until the time and opportunity for a cure have passed.

DOUBTING INSANITY (*Folie du doute*, *Maladie du doute*, *Grübelnsucht*) is classed by Régis¹ as a form of melancholia (*mélancolie délirante*), on the ground that it has the three elements of melancholia—namely, fixed ideas (*délire*) of a sad nature, general mental depression, and tendency to suicide. The melancholia is secondary, however, rather than primary, and doubting insanity belongs more properly under the head of a psycho-convulsive mental disease closely allied to delusional insanity, like which it is more commonly a manifestation of psychoneurotic heredity, appearing for the most part among the cultivated classes. It consists in an uncontrollable doubt and indecision, unanswerable by any degree of rational explanation, regarding the occupations, duties, or events of the day, religion, a future life, the commonest acts, or the most abstruse problems of life. Doubting insanity essentially depends upon an anomalous action of the will, with imperative conceptions and impulses. It is classed by some writers as a monomania of the degenerative type. Schüle calls it *Verrücktheit sensu strictiori*, using the term *Verrücktheit* also for the three forms of primary delusional insanity just described.

Délire du toucher, an insane dread of touching certain objects, and the morbid fear of defilement, called by Hammond *mysophobia* (similar names may be multiplied indefinitely), belong in the same category.

There are mild cases of all these forms of disease, which seem like simple weakness of character, others requiring for treatment the conveniences of the retreat for nervous and mental diseases, with a fair prospect of recovery, and still others tending to chronicity in which hallucinations, delusions, and dementia appear only as a further development into another form of insanity. They may, in mild degrees, be symptoms in the course of other mental diseases, especially melancholia, like many other manifestations of morbid mental energy, such as Doctor Johnson's inability to enter a room with his left foot first or to pass a lamp-post without striking it with his cane, etc.

PRIMARY MENTAL DETERIORATION OF PRIMARY BRAIN ATROPHY is a term suggested for a curable impairment of the mind arising from brain-exhaustion in persons, usually men, between the ages of from fifty-five to sixty-five. I have found it in some cases associated with interstitial nephritis and with degenerative disease of the walls of the heart, and have suspected atheroma of the cerebral arteries or possibly endoarteritis of specific or other origin. It occurs at a time when atrophy of the brain is naturally taking place. There are the usual indications of physical wear and such marked deterioration of the mental powers as to

¹ *Manuel pratique de Médecine mentale.*

seriously interfere with the capacity to attend to customary business and every-day duties, and to closely simulate the early stage of paralytic dementia. There occur also, in a certain proportion of cases, epileptiform convulsions, slight attacks of dizziness, petit mal, and always disappearance of sexual power and desire. There may or may not be headache. The patient recognizes his condition, his mental depression does not far exceed the physiological limit, and there is no reasonable risk of suicide, except from reasons which would impel a sane man to it.

Under the influence of rest, if begun early, tonics, and a strict regard to the laws of health the symptoms commonly disappear if there is no organic disease. I have never seen the brain recover its tone to the extent of making it safe or even possible to resume the previous kind and amount of work. In a certain proportion of cases there is striking mental impairment, even dementia, and the primary atrophy of the brain sometimes makes rapid progress to unconsciousness and death.

It is not possible to say, by the degree of atrophy found post-mortem, whether there was or was not primary mental deterioration during life.

The TREATMENT consists in entire freedom from care, rest from work, travel, tonics, etc.

As mental disease is more than a brain disease, and is a disease of the intellect, each age from infancy up (and each individuality) impresses its peculiar mark upon it, and there are certain terms in common use to express insanity associated with certain physiological processes whose meaning should be explained.

INSANITY OF CHILDHOOD is for the most part only a further development of a congenital state of mental defect. I have seen, however, well-marked mania, melancholia, primary dementia, and primary delusional insanity before the age of puberty. Typical acute mania I have seen twice in children two years old, apparently arising in normal brains after severe injuries to the head. This is quite uncommon, and the number of cases thus far observed is too few to make me feel sure that my own experience of a favorable result as to recovery in uncomplicated cases will be generally confirmed. At best, after a cure there is a more or less decided arrest of brain development.

HEBEPHRENIA (insanity of pubescence and adolescence) occurs within the ages of fourteen and twenty-three or thereabouts. Like insanity in general among persons in early life, it most commonly indicates an hereditary predisposition to mental or nervous diseases or an early-developed brain defect or injury, possibly an exalted emotional state or an increased nervous sensitiveness produced by masturbation. It is a mild form of primary dementia, modified by the mental changes going on during adolescence. Indeed, it is simply an exaggeration and prolongation of the curious psychological development of that period, too well known to need description, which goes on in the most insidious way possible through months or years of what seems silliness, absurd fancies, foolish sentimentality, egotism, impaired common sense, and diminished judgment and self-control, to a slowly-advancing dementia, which even then is not always recognized as disease. The result is an arrest of brain development on various planes of intellect, and a preservation of the youth's tastes and sense and intelligence, as modified by the morbid propensities characterizing an unhealthy development of the change from boyhood or girlhood and

youth to adult life, with the adult's strength—a curious combination of intellectual brightness, it may be, with lack of mind. For this characteristic condition Westphal uses the expressive term *Permanenz der Flegeljahre* (permanence of the usually transitory state, which then commonly results in permanent arrest of brain development on the plane of the mind at a definite age of adolescence); and yet there may be more than that—mental deterioration, which in years may lead to pronounced dementia. Cases of primary dementia occurring within the years of puberty and adolescence are often classed as hebephrenia and conversely, so that one term, primary dementia, is thought sufficient by many writers on insanity.

In the early stage there is sadness, hardly amounting to melancholia, and it usually constitutes an important symptom to the end, although, like all the other changes in the mental state, it is superficial to the extent of at times seeming almost insincere. Masturbation is common. Occasional outbursts of violence are also common, often with mental confusion, incoherence, or stupor, and in severe cases there occur, usually, attacks of temporary fury, with distressing or agonizing hallucinations of sight and hearing, and delirium, which may all last for a very short time or for a number of days. In young women and girls these outbursts may be coincident with menstruation or in the intervals. The countenance loses somewhat in expression in all cases, and becomes almost vacant or quite so in those in which the dementia becomes well marked. A mild form of the disease is quite common, and consists in an undue intensity or a prolongation of the curious psychological phenomena commonly observed during adolescence. It is marked by aimlessness, changeability, self-assertion, exaggerated self-consciousness, with, perhaps, propensity to lie or steal or run away from home, and ending without any apparent damage to the mind, except that the individual is less of a success in life than he would have been but for his illness.

The course is slow, and although in the majority of cases mental impairment is arrested before reaching what may be properly called complete dementia, in well-marked cases the duration of the disease is long and its results last for life. In many cases progress continues with extreme slowness to extinction of the mental faculties. Oftener the individual simply, in a certain sense, fails to reach that stage of intellectual maturity and strength which he otherwise would have attained. It is not always easy to draw the line between the psychological and the pathological changes that take place during the years of adolescence, and there are many mild cases of hebephrenia in which various kinds of failure in life are due to this disease rather than to the faults or vices to which the failure may be attributed.

In TREATMENT irritability, restlessness, absence of a power and sense of responsibility, and sleepless, excitable nights, are the most difficult symptoms to combat. The restlessness and irritability often lead to refusal to be reasonably controlled and to a tendency to wander away from home with theatrical displays, so as, in the case of girls particularly, to require restraint, especially if the excitability should be so great as to amount to outbursts of violence or should lead to sexual improprieties.

The fact should be borne in mind that there is a diseased brain which needs nutrition, rest, and discipline, which must be proportioned to suit each case. Outdoor, simple life, with sea-bathing, carefully-selected diet,

without too much meat, exercise, mental training limited to the requirements of each patient, are the chief reliances. Iron, cod-liver oil, and arsenic are useful tonics. Stimulants, including tea and coffee, should be avoided. Quiet nights and necessary repose can be secured by bromides, exercise, and opiates used sparingly, which also control the impulse to masturbation. A sound education, a healthy experience of the rough and tumble of youthful life, and the careful avoidance of processes and habits of indulgence will often prevent the symptoms of disease from growing into traits of character and habits of life. On the other hand, in some cases there is a half-conscious struggle between the fine traits of character and the demoralizing influences of the disease, and a most pathetic effort to keep the better nature's supremacy over the lower impulses set free or developed by the destructive tendencies of a fearful malady.

MENSTRUAL INSANITY differs from other periodic insanity in not being necessarily a further development of an hereditary or acquired state of mental degeneration, and in being curable in a fair proportion of cases.

INSANITY OF GESTATION, PUERPERAL INSANITY, AND INSANITY OF LACTATION do not call for any further comment than the remark that they represent causes and conditions rather than types of disease.

CLIMACTERIC INSANITY in women and in men is usually a curable folie raisonnée—insanity of action or affective insanity, which may develop into secondary dementia or chronic insanity with delusions. It does not necessarily include all acute forms of insanity occurring at the climacterium, but only those slowly developing with the physiological changes going on.

The course is usually subacute, the duration a couple of years or more, and the termination in about half the cases is in recovery. Permanent change of character and further progress to incurable insanity are perhaps about equally common.

TREATMENT consists in a sedative and fattening diet, simple, healthful conditions of life. Removal to an asylum or some form of restraint is needed where the conduct is such as to demand seclusion and control.

SENILE INSANITY arises in suspicions and a generally deluded state of mind regarding those persons whom there is every reason to trust—namely, relations and near friends—and as extraordinary credulousness of designing persons whose interest and character would naturally suggest being on the guard against them. There is impaired judgment, as shown by the mismanagement of property and diminished capacity for business, usually some perversion of the sexual instinct. The suspicions and credulousness in time amount to insane delusions, and if life lasts the end is in marked dementia. But there may be no mental impairment evident to casual observers or to ordinary acquaintances for many years. The improper relations assumed with the opposite sex, the neglect or abuse of those nearest by ties of blood, the squandering of property on strangers, and the omission to provide properly for the members of the family, are wrongly attributed to a character become bad rather than to destructive brain disease, where they belong. Not seldom senile insanity is a moral insanity, and shows itself by an entire change of character not explainable by other circumstances than disease, and is then marked by

indecent exposures, loss of the fine sense of the decencies and proprieties of life, destruction of the discriminating power between right and wrong acts.

The course of senile insanity is slow, unless there be also some fatal disease with it, and evident mental impairment may be so late that the disease may be overlooked for years.

The TREATMENT is abundant nutrition, including wine, removal from irritating conditions of life, protection of the individual against himself, and guarding the community against harm or indecencies. Small doses of morphia daily are often of great benefit, and there is no real danger of acquiring the opium habit if reasonable discretion is exercised in its use.

SENILE DEMENTIA is simply an excess of the natural mental weakness of old age out of proportion to the bodily state, an exaggerated childishness of senility to the extent of producing irresponsibility. It is in reality a subacute primary dementia modified by the peculiarities of old age. Memory fails first, and a condition of general weakness of mind follows rapidly afterward. Secretiveness, suspicions, delusions, and hallucinations of the special senses are almost always present.

It is not uncommon for the early symptoms to consist in an inhibition of the higher faculties of the mind, so that the lower impulses become prominent. The sense of right and wrong and the moral perceptions may become entirely weakened. Acts of indecency, dishonesty, injustice, depravity may follow impaired judgment, and yet so far precede strikingly perverted memory and general intelligence as to make the insanity, which is obvious to an experienced observer, entirely fail to impress itself upon the minds of the community.

The TREATMENT consists in caring for the comfort of the patient, which can usually be done at home or at least in a private family, unless there are persistent impulses requiring the control of an asylum. The preparations of opium are useful to control extreme restlessness, and may be given freely, avoiding narcotism. A bland diet of fattening food is best suited to the wants of the aged. A simplified life often serves every purpose, especially in the quiet of the country, although it is best not to remove them from familiar scenes unless as a matter of necessity.

Complicating Insanities.

Complicating insanities simply add to the usual symptoms of the special forms of mental disease many of the characteristics of the particular disease, rheumatism, gout, phthisis, organic diseases of the heart, etc. Choreic movements depend upon the same pathological changes as are found in the sane, and certain diseases are attended with such profound changes in the nutrition of the brain as to give rise to mental impairment, which amounts to almost extinction of the mind, such as myxœdema and chronic nephritis. Acute mania occurs in the last stage of Bright's disease, which may be difficult to differentiate from uræmia. Mania, melancholia, and delusional insanity occur in the course of acute febrile diseases or appear during the period of convalescence; in the latter case the prognosis is much more unfavorable than in the former. The close

alliance between insanity and pulmonary consumption is a matter of frequent observation. The two diseases are interchangeable, and they often coexist. The relation between rheumatism and insanity is less close.

Insanity from Specific Poisons.

Maniacal symptoms have been reported from the use of various drugs, including iodoform, mercury, etc. Hasheesh dementia is not uncommon in the East. Acute delirium arises from hydrate of chloral and the preparations of opium analogous to acute alcoholic mania from excessive drinking, and chronic impairment from their prolonged use. Bromide of potassium rarely produces symptoms similar to those of mania; taken for a long time in even moderate doses, it tends to mental sluggishness, and in long-continued large quantities given uninterruptedly there is a danger of well-marked dementia.

All of these conditions may be prolonged beyond the usual action of the particular drug or give rise to symptoms in excess of those usually observed. The characteristic indications of the particular drug, sometimes marked by the combined use of several, will be found if they are carefully looked for.

The TREATMENT consists in breaking off the bad habit gradually or abruptly as each case may require, and in otherwise treating the persisting symptoms in accordance with the general principles already stated in considering the various mental diseases.

ALCOHOLIC INSANITY includes mental disorder from the use of alcohol in both the acute and chronic forms.

Acute alcoholic mania may come from a single excess in drinking, which in some individuals is always attended with maniacal symptoms. It may constitute the alcoholic trance described under the head of Transitory Insanity. From long drinking and exhaustion or by withdrawal of the accustomed stimulant we may have the familiar mania-a-potu or delirium tremens.

Under the prolonged use of alcohol primary delusional insanity, melancholia, mania, and dementia occur.

From long-continued drinking of alcohol, even to slight excess, for many years, it is rare not to find some mental impairment, if only an "uncontrollable violence of the instincts and emotions," a sort of moral insanity.

The PROGNOSIS is more favorable than in most forms of insanity uncomplicated by the abuse of alcohol, especially in the case of primary delusional insanity, if the bad habits can be effectually corrected and if the alcoholic excesses have not been continued long enough to produce organic changes in the cerebral blood-vessels. In the latter case the dementia sometimes simulates that of general paralysis so closely as to be called pseudo-paralytic dementia from alcohol.

TREATMENT is rarely successful outside of some asylum.

SYPHILITIC INSANITY does not properly include those cases of mania, melancholia, and delusions of persecution of the ordinary type of which the exciting cause is found in the train of thought aroused and kept up by the consciousness of having contracted syphilis, but only such as

depend upon the presence of the syphilitic poison in the system. There are no diagnostic marks to distinguish it from insanity not caused by syphilis, except in a certain proportion of cases of organic syphilitic disease of the brain.

The PROGNOSIS is rendered much less favorable from the fact of the syphilitic cachexia.

In addition to the usual means of TREATMENT for the several forms of insanity, the appropriate measures for syphilis should also be tried, except where there is evidence of diffuse organic disease.

Organic Mental Diseases.

GENERAL PARALYSIS OF THE INSANE is a disease marked by definite pathological changes in the central nervous system, chiefly in the cortex of the brain, but which may extend to any part of the cerebro-spinal tract or to the sympathetic ganglia and cranial and spinal nerves. Its constant symptoms are—(1) vaso-motor disturbance ending in vaso-motor paresis; (2) mental impairment, which makes progress, for the most part unevenly, to complete terminal dementia or extinction of mind; (3) impaired muscular control, which advances more or less uniformly to almost entire paresis or nearly total paralysis. Expansive delusions, the delirium of grandeur, megalomania (which may change suddenly to micro-mania), or simply a feeling of elation, happiness, self-satisfaction, or undue complacency, are found, but often not until or near the end. The other symptoms vary in individual cases within a wide range, so as to simulate almost every form of insanity; and it is quite possible that they include what a more exact pathology will hereafter recognize as several distinct diseases.

SYNONYMS.—General paralysis is also known as general paresis, progressive paralysis of the insane, paretic dementia, paralytic dementia, cirrhosis of the brain, paralysie-générale, folie paralytique, démence paralytique, periencephalite chronique diffuse, meningo-myélo-encephalite chronique interstitielle diffuse, encephalite généralisée, periencephalite chronique diffuse, encephalite interstitielle diffuse, encephalite avec proliferation sclereuse interstitielle, Allgemeine Paralyse, progressive Paralyse der Irren, chronische progressive parenchymatöse Encephalitis der Rindensubstanz, pericerebritis, periencephalo-meningitis diffusa chronica, periencephalo-myelitis chronica diffusa, encephalitis interstitialis corticalis, paralytische Blödsinn, primäre Encephalitis interstitialis mit Ausgang in Sclerose. Griesinger placed general paralysis among the complications of insanity. It is popularly known as softening of the brain (*Gehirnerweichung*).

HISTORY.—The combination of the two series of symptoms, paralysis and dementia, was recognized by Haslam, and at the beginning of this century by French writers, who also knew their fatal import. Esquirol describes a typical case of general paralysis of the insane under the head of monomania in his *Maladies mentales*. His pupils, especially Bayle and Calmeil, have studied and described general paralysis. At the time of his first visit to England, forty years ago, the late Luther Bell had never recognized a case, and there can be no doubt of the fact that it has

rapidly increased, particularly in the last dozen or twenty years, with the rapid increase in the aggregation of the population.

ETIOLOGY.—So far as heredity is concerned, general paralysis has not such close relations with mental diseases as insanity in general. It is estimated to be hereditary, in the sense of being closely related to other forms of insanity, about one-half as often, and it is nearly allied to apoplexy and epilepsy. My own experience leads me to the conclusion that in those cases of general paralysis without a previous history of syphilis (and the same statement is true in less degree of persons who have had syphilis) the vast majority occur in families in which there have been cases of insanity, epilepsy, or apoplexy. It is rare among people living simple agricultural lives, but is intimately connected with the faults and vices of civilization—specialized overwork, involving strain in the office, study, factory, mine, etc., especially if to bodily exhaustion and brain wear and worry there be added hard living and hard drinking, sexual excesses, and syphilis. The Scotch Highlander rarely has the disease until he comes to Edinburgh or Glasgow. In Ireland general paralysis is so rare that of 9271 cases of insanity in 1882, only 6 were general paralytics, as compared with 1151 out of 13,581 in England the same year; during which, in Scotland, of 238 deaths from insanity, 10 were from general paralysis; but the Irishman has no special exemption from general paralysis in American cities or in large English towns and mines and factories, where he works hard, drinks hard, and lives hard generally. It is, so far as I am able to learn, unreported thus far among our negro population until they come to the great centres of population; it is said to have been unknown among the slaves. Among the English, Scotch, and Americans it prevails most among those people who are in, or who have dropped down to, the lower strata of society. Of 2212 private patients in England, 139, or about 6 per cent., were general paralytics, while 1012, or about 9 per cent., were found among 11,359 pauper patients. French and German writers report it as most common among the brain-workers. In women of the upper class it exceedingly seldom occurs. In some of our Western asylums not more than 1 or 2 per cent., or even less, of the patients are reported as general paralytics, coming chiefly from farms. In the asylum for the centre of the manufacturing districts of Massachusetts about 9 per cent. of the patients are general paralytics. From the iron- and coal-mines of England from 14 to 17 per cent. of the insane confined in asylums are general paralytics. It is more common in cold climates than in warm, other things being equal. From one-sixth to one-tenth of the cases, varying in different localities, are women.

General paralysis not only is most frequent in the stronger sex, but it selects the strong individuals in the prime of life, between the ages of thirty-five and fifty. It is extremely rare under the age of twenty, although Turnbull has reported an unique case at the age of twelve;¹ it is not common under thirty or over sixty; I have seen two cases in men sixty-five years old. It is seldom seen in individuals who have been weak from childhood, unless as the probable result of syphilis.

The excesses of the habits of the city and of mining and manufacturing centres, hard work, high living, late hours, predispose to general

¹ *Journal of Mental Science*, October, 1881.

paralysis in strong constitutions at the period of their greatest activity, especially if the physical strain, the violent struggle for existence, has begun early in life with insufficient food and excessive work, and if ordinary paralysis be not uncommon in the family. Alcoholic and sexual excesses are considered to be particularly common predisposing causes. Recent investigators find syphilis to be a part of the antecedent history of from one-half to three-fourths of the cases, but chiefly in those slowly advancing or subacute from the beginning. By some writers syphilis is considered to be in those cases only a diathesis, as is held by Fournier, or a debilitating antecedent, like chronic malarial poisoning. Others think that so large a proportion can be accounted for only by some specific relation between the two diseases. If the fact so often stated is true, that syphilis is rapidly increasing, perhaps part at least of the increase in general paralysis can be thus accounted for.

Mental shocks of various kinds, excessive emotional strain with mental exhaustion, and injuries to the brain, are the commonly reported exciting causes of general paralysis, but it is not certain that—in many cases, at least—they do more than hasten the pathological process and call attention to the symptoms. So far as my observation goes, the injury to the head, supposed to be the cause of general paralysis, often has appeared to probably come from an accident due to the impaired physical strength and to the vaso-motor disturbance in the brain incident to the early stage of the disease and while it was still unrecognized. Cases are observed in which no predisposing or exciting cause is found by the physician. I have seen it following diphtheria and other debilitating diseases, after long exposure to malaria, and apparently due simply to prolonged mental strain in persons otherwise living in moderation under circumstances exceptionally favorable to health.

SYMPTOMATOLOGY AND COURSE.—As a rule, to which the exceptions are few, the early symptoms of general paralysis are obscure. Their appearance and progress are so gradual and insidious that they are usually overlooked for a period varying from several weeks to a year or more, sometimes for four or five years, perhaps even longer. There is a slight change in character, which is frequently attributed to wilfulness or perverseness arising from some disagreeable circumstance; to want of a reasonable attention to the little affairs of daily life; to indifference, temper, carelessness, or recklessness; to a want of aptitude and receptivity having an ethical rather than medical significance; to an impaired moral sense. The patient may be observed to be simply more quiet and heavy; inclined to be depressed rather than distinctly melancholy; a little heedless; unusually indifferent, and indisposed to worry over things that formerly would have disturbed him; drowsy or dropping off to sleep at work or in the theatre; disturbing the household by his restlessness at night—in and out of bed, up and down stairs, for trivial and yet not seemingly insane reasons. He may become easily disturbed by trifles, and yet careless to more important matters. He begins to overlook, perhaps rather than forget, recent little things. His power of attention is diminished, his will weakened, his self-control impaired. He becomes less careful of the niceties and proprieties of life, less interested in his family and all that is nearest to him—self-absorbed, egotistic, indulging in inconsequent stories and remarks. Although the memory is not dis-

tinely at fault, fresh impressions do not make their usual imprint on the mind. His moods are unnaturally changeable. A certain slovenliness in habits or carelessness in dress, an inattention to customary little courtesies and attentions, slight yet noticeable, are not uncommon early symptoms of general paralysis. There is soon observed, often noticeable to the patient, a lack of endurance, an early sense of fatigue from exertion, a sense of muscular prostration, physical discomfort, or general pains which may be attributed to malaria or rheumatism. Commonly, not always, there is disturbed sleep or restlessness. There may or may not be headache, slight or severe, transient or persistent. There may be a sense of pressure or an uncomfortable feeling about the head, especially the forehead, or it may be the seat of no pain or discomfort whatever. There may be a slight or severe local or general sensation of distress or uneasiness in the head after mental effort only. There is often pain, anæsthesia, hyperæsthesia, paræsthesia affecting any sensitive nerve, often none at all, or impaired muscular sense.

The average daily temperature is higher in general paralytics than in health. It is sometimes lower, and the range is greater than the normal. In the only extremely rapid case which I have seen (two months in all) it was 97° F., and thereabouts for a number of days, and then rapidly rose to 103° and 104°, where it remained until near death. After the congestive, epileptiform, and apoplectiform attacks it rises from two to seven degrees, and remains high for a considerable time, while in pure epilepsy it quickly falls. This difference, however, is not sufficient, as between epilepsy proper and epilepsy as an early symptom of general paralysis, to establish the differential diagnosis with certainty in all cases.

The vaso-motor disturbances in the brain are indicated by transient congestions or local anæmia, dizziness, faintness, temporary outbursts of anger, excitement, or confusion, and rapid changes in the mental and emotional state. Convulsive attacks are not common in the early stage of the disease, except in those cases due to syphilis, but may occur, and may so resemble hysteria, petit mal, epilepsy, and apoplexy as to be confidently diagnosticated for those diseases. The emotional state is of indifference, despondency, gloom, melancholia, elation, a feeling of self-satisfaction, or mania.

The symptoms thus far are not clear except on minute examination. The family and most intimate friends of the patient observe that he is changed, but cannot tell how, and are apt to say that he is not the same man that he was, that his troubles have been too near for him, that he does foolish things as never before, etc. Sometimes he estimates his symptoms correctly, sees the downward change himself, and is oppressed by it; oftener he is indifferent to it, or still oftener quite well satisfied with his condition and prospects, or even mildly elated. He may squander his fortune, ruin his reputation, become addicted to drink. His sexual appetite, not held back by his normal power of self-control or exaggerated with a general physical and intellectual crethism, may lead him into all sorts of improprieties and immoralities or to exhausting excesses, which are perhaps more common among the married than among the unmarried; and yet his disease is not recognized, because the later symptoms of general paralysis—namely, grand delusions, staggering gait, tremor, and marked dementia—have not yet appeared.

The pianist loses his skilled touch ; the actor fails to learn a new part ; the ready salesman no longer has his great facility of selling ; the singer does not see that his notes have become false and harsh ; the engraver's fine lines are no longer possible to him ; the preacher reads the same hymn three times in his Sunday service ; the man of promptness fails to keep his appointments ; the speech seemingly clear to others becomes indistinct to a deaf wife ; the eye trained to close, exact work loses its capacity of fine distinctions of form or color ; the expert accountant can no longer add up his three columns of figures at a time ; the doctor writes prescriptions showing unwonted carelessness or impaired judgment to the extent of injuring his practice ; a banker loses his property by foolish ventures ; the saving business-man buys quantities of useless articles ; the moral man becomes licentious or the temperate a drunkard ; the respected father of a family goes to the State prison for running off with a pretty servant-girl ; the lawyer ruins his client's cause ; the considerate husband shows unwonted harshness and violence to his wife ; the industrious worker becomes a tramp or a vagabond ; the amiable friend becomes irritable, disagreeable, perverse, hard to please, easily excited, cranky. These are some of the facts I have known to occur in the early stage of general paralysis without giving rise to the suspicion of cerebral disease, the conduct of the individual generally not suggesting insanity. In one case the cerebral vaso-motor disturbance caused marked intoxication from a small amount of wine, previously taken habitually without showing it, for several weeks before the most careful examination revealed other indications suggesting general paralysis. In the upper walks of life, wherever a nice intellectual adjustment or fine muscular co-ordination is required in the daily duties, symptoms to put the physician at least on his guard against general paralysis will rarely be overlooked in this early stage of the disease if they are sought for with sufficient care and appreciation of their import. In proportion as the employment is coarser, and not requiring much mental or muscular exactness, the symptoms are more difficult of correct apprehension, until we get to the day-laborers, in whose dull nervous organizations quick reactions do not occur, and in whose simple labor, requiring little thought and only muscular co-ordination of a low grade, a partially demented brain and muscles considerably impaired in strength serve their purpose so well that an early diagnosis is next to impossible. Routine work, to which he is long accustomed, is often done well by a general paralytic, provided it does not require exact mental or muscular co-ordination, when the disease has so far advanced that any new work except of the simplest kind could not be performed.

It is seldom that general paralysis, in its early stage, receives careful enough attention to be recognized or to create a suspicion of its existence until exhaustion, a long period of sleeplessness, perhaps a violent shock, a strong emotion, a fall or a blow, a congestive attack, an epileptiform seizure, an apoplectiform convulsion, or some unknown cause—probably a vaso-motor disturbance in the brain—hastens the progress of the disease, and the previously slight or obscure symptoms (at least some of them) are suddenly so aggravated as to make them of unmistakable signification. It is usual in such cases to date the appearance of general paralysis from this point, and to overlook its previous existence for the weeks, months, or it may be years, of its prodromal period. It is espe-

cially easy to overlook the period of invasion of general paralysis of the insane, as the symptoms may, and generally do, have that temporary, transient, and variable character which is common to diseases or stages of disease in which vaso-motor disturbances predominate; inasmuch, also, as the individual character has to be taken so much into account in estimating the import of particular symptoms, and as few or many of the leading indications of general paralysis may be present in a particular individual, while the physician might happen to make several examinations of his patient at times when the symptoms did not appear at all. For now and then all symptoms absolutely disappear in a time which may be short or long. In two cases of general paralysis in the period of invasion, where the moral perversion was said by the other members of the family to be a source of great trouble, I sent both patients to an insane asylum entirely upon the statements of their wives, without being able myself to see any evidence of insanity, but where the clinical history of general paralysis in its early stage was so accurately given that I was sure there could be no mistake; and a few days' continuous observation in the hospital showed the diagnosis to be correct.

The dementia, ataxia, and muscular impairment of the prodromal period of general paralysis of the insane may be masked by the prominence of almost any of the symptoms of nearly all the mental diseases; and many of the indications of the prodromal period are symptoms of disease only as they are departures from ordinary customs and habits, although in other persons they might be quite the reverse and natural to their daily life. Much that might be done by a general paralytic with great care in the early stages may quite resemble the careless work of the same person in health.

The following case is quite typical of the development of general paralysis of the insane:

Mr. ———, age 52, married, a clergyman: his mother died of apoplexy; two of his four brothers are insane. He had the usual illnesses of childhood in mild form, diphtheria of the worst type in 1869, and in recent years, according to his belief, malaria, as he had lived in a malarial region eleven years. As a young man he was of robust frame and vigorous health, brought up on a farm. He overworked, denied himself, and overtaxed, in getting his education, a brain not trained from early years to exacting labor. Eight years ago, for the first time, and at intervals since then, he has had attacks of mental confusion, dimness in sight, and indistinct articulation lasting from a few moments to several minutes. Three years ago, after great emotional strain, people began to notice that his preaching had lost in animation and force, and they complained that he had suddenly become more radical in his views. Great mental worries occurred soon after. There had been no alcoholic or other excess, except of mental overwork, and there could be no reasonable possibility of syphilis, unless we adopt Hebra's dogma, "*Jeder Mensch kann syphilitisch sein*"—that the means of innocently acquiring that disease are so widespread that no one can be said to be free from the danger of it. Nearly two years ago, in the dark, while feeling tired mentally and physically, but not ill or dizzy, in alighting from a coach he missed the step and came to the ground on his feet with great force. He walked to the house of a friend, and was found by one of the family on their entry floor

groaning, but not unconscious. He could not stand or talk, vomited incessantly, and complained of a horrible pain in the back and top of his head. Two days later, and each succeeding Sunday, he preached, obstinately and unlike him refusing to listen to advice to keep quiet; but he remained in bed between Sundays for three weeks, when the striking symptoms disappeared; but he had never felt entirely well since then—never had the same animation. He was supplying various pulpits, and found, wherever he had preached before, that people complained that there was a general lack of vigor in his preaching. Two years ago he observed that his right leg had less life in it than was natural, and soon after that both legs seemed heavy—that it was less easy to run up and down stairs, which his wife also noticed several months later. He also has had for a year a strange feeling, a sort of numbness, in his legs. He thought that his handwriting and speech have continued as good as ever, but has observed that he has had to change to a stub pen, as he found difficulty in writing with the old sharper-pointed kind; that his voice had grown less clear; and that he has rapidly become far-sighted. He has never had any dizziness, pain, ache, or uncomfortable feeling about his head, except during the attacks already referred to. There have been no thoracic or abdominal symptoms, no neuralgia or rheumatism. Appetite and digestion have been faultless. He has lost about ten pounds in flesh. He has slept soundly, but is often restless, getting in and out of bed. He says that he was depressed for lack of employment; that he is not irritable, but that his family would say that he is not as tractable as he was, not as patient, less easily satisfied; that his son and wife would say that he is not what he once was—that his memory is not as clear and vivid as it was. He is conscious that within the last two years he has had violent, uncontrollable passionate outbreaks from trivial causes. He preaches his old sermons, because he thinks they are too good to be lost, and because he takes pleasure in rewriting them, in doing which he remarks that the handwriting becomes progressively worse toward the end of each sermon. He says that he can write still better sermons, but does not like to make the effort. When he went into the pulpit a week ago he was told not to announce a second service, but everybody seemed to him so pleased with his preaching that a week later he gave word that there would be an evening service, to which, he laughingly said, only one person came. In standing with his eyes closed and feet together there was a little unsteadiness. On attempting to turn around or to stand on one foot with eyes closed there was some, not very great, ataxia. In these trials the unsteadiness and ataxia soon became very striking on prolonging the muscular effort a few moments. His hands had a powerful grasp, each marking 74 with the dynamometer, and on being stretched to their full extent, with fingers spread, immediately thereafter the fibrillary tremor could be seen only on close examination. There was no marked tremor of the muscles of the lips or face, except in movements which placed them at extreme tension. The tongue was quite tremulous on being protruded to its full length and held there. In walking in a rather dark entry the steps seemed to me shortened and the feet wider apart than in his natural gait, and he did not raise his feet as much, which he noticed also. In going up stairs he placed the whole foot, heel and all, on each step to keep his balance. He turned very deliberately,

keeping the feet near together and not raised from the landing. On coming down he evidently steadied himself by a muscular effort extending to his head and shoulders. The knee-jerk was well marked and alike in both legs, but I could not say that it was exaggerated. There had been no change in the sexual function.

His general mental state seemed to me to be of a quite superficial kind of despondency at his prospects, and yet absence of a corresponding degree of anxiety for the future; of satisfaction with his ability and worth; of a feeling that his family are unduly anxious about him; and of a prevailing state of inappreciation of the whole situation, and of a general state of happiness which was abnormal—an opinion which his wife afterward corroborated. He was quite emotional, and easily and rapidly moved to smiles, and from them almost to tears.

In explaining his restlessness at night he stated that he was taking quinine for his malaria, and that it acted on the liver so as to increase the flow of urine, which he repeated several times, but laughingly said, "Of course; how foolish!" when I suggested that he meant the kidneys. In removing his clothes for a physical examination I found that he had two starched shirts on—the one in which he went from home, and that in which he preached, in order not to rumple the second one. When I asked why he could not take home a soiled shirt in his valise after having brought a clean one in it, the idea struck him that he, after all, had done something foolish.

The examination of chest, abdomen, and of the urine was negative. I could not find anywhere evidence of anæsthesia, hyperæsthesia, or paræsthesia, general or local. The reaction of the muscles to the faradic current seemed normal. By ophthalmoscope and otherwise the eyes showed only the emmetropia already referred to. Hearing was also normal, as well as the other special senses. In a close examination I could at first not discover anything about his speech more than an extreme deliberation in articulation, which might perhaps have been natural to some scholarly men, but which I afterward learned had been only of recent origin, and increasing. It was more pronounced after the patient became a little wearied, and then I found that he could not articulate a long word with several labials and linguals without manifest difficulty. I gave him a sheet of paper and asked him to write from top to bottom. He could not think of anything to write. When I told him to put down the text of his sermon of the previous day, he could not possibly remember it; no more could he call to mind a sentence or a sentiment from it. What he wrote is marked No. 1. His normal handwriting, No. 2, is of the date of 1881. Nos. 3 and 4 were copied from an old sermon a few weeks previous to his visit to me, and are taken respectively from the first page and the next to the last of the copy. The facts may be observed that the old handwriting is quite free, with an easy sweep of the pen. In the copy of the sermon the first page shows that the pen is held stiffly and tightly, and that the lines are not made with as steady a movement of the hand as in the old handwriting. The lower lines on the first page are a trifle worse than the upper, and pretty much like the second and third pages, from which there is progressive deterioration to the end. The page written in my office was very carefully done, and, under the circumstances, is marked by such muscular unsteadiness and evidence of mental

impairment and enfeebled memory as to be almost, if not quite, of itself pathognomonic of general paralysis.

I purposely made no remark to the patient, and he made no inquiry, about diagnosis or treatment. He would have missed his train, although there was a clock in my office, had I not reminded him of the late hour, whereupon he made all his arrangements with care, good judgment, and accuracy, and reached his home safely. As he walked briskly down the even sidewalk I doubt whether any one, even a physician, would have remarked any unsteadiness or anything abnormal about his gait. If he had been followed a few blocks, until the idea of catching his train had ceased to stimulate him, and after he had reached the crowded thoroughfares of the city, especially as he stepped up and down curbstones or walked slowly to avoid teams at crossings, a close examination would undoubtedly have shown the defects in gait already pointed out.

Mr. ———'s wife had noticed that her husband did not raise his feet as of old in walking—that he walked as if they were heavy, but under the influence of coca wine or a decided mental stimulus he walked apparently as well as ever for a short distance. She had noticed a slight impairment in memory, an increased fractiousness, a diminished ability to appreciate things in their proper light, a changeability in his moods and mental state, a scarcely-observed but noticeable neglect or oversight of little customary duties, occasional passionate outbreaks from trifling causes, a disposition to laugh and cry easily; and that often he did and said unwonted foolish little things, like attributing increased flow of urine to his liver, wearing two starched shirts, announcing the Sunday evening service; but she had not considered any of the symptoms as evidence of disease, especially as he kept accounts, attended to his preaching, etc., and showed no manifest indications of a disturbed or impaired mind. She had remarked a decided change in the character of his handwriting, also an unusual deliberateness in speech, but no indistinctness or hesitation, although his voice had become less clear. He had had no delusions, illusions, hallucinations, or unreasonable ideas. It was for the weakness in his legs that she asked my advice.

I found that the mental and cerebral symptoms in this case had been overlooked, and that the weakness in the legs had been attributed to spinal concussion, for which a favorable prognosis had been given.

I examined the patient after he had been away from home nine days, preaching two Sundays, and making many new acquaintances in the mean while, besides having travelled nearly two hundred miles by rail, so that he was fatigued. After three weeks' complete rest I saw him at his house. The knee-jerk was increased as compared with the previous examination. Otherwise the symptoms had so ameliorated that some of them could be brought out only after a long and patient examination, and the rest had to be accepted as a matter of history of the case. I had his photograph taken, and by comparing it with another taken three years previously his family noticed what was quite obvious in that light, but what had thus far been overlooked—namely, that the facial muscles had lost very much in expression.

The specimen of handwriting marked 5 is of a gentleman in whom the paralytic speech is quite evident after a half hour's talk, but quite masked in the beginning of a conversation, when rested. It is written

with care, after a long rest, and, as compared with his former writing when done with equal care, there is seen only a wider separation of the letters. Its general appearance, on casual inspection, is better than that of his ordinary writing before his illness, as that was hurried and careless. But the second or third page brings out the ataxia distinctly. It shows how well a general paralytic, under the influence of rest and quiet, may control certain groups of muscles—how completely the ataxia may be concealed under an ordinary examination; and yet the symptoms in his case may be clearly brought out by the method just described. The tongue was quite tremulous.

The writer of No. 6 was more advanced in general paralysis, but had been thought not to be ataxic, from the fact that he had been able to write a single word pretty well. His few lines are quite characteristic of a general paralytic. Although he was in my office in Boston, he dated his statement from his home, and wrote the word Lawrence not badly for a man not in the habit of writing much. Seeing me for the first time, he addressed me as Friend Folsom, and he signed his name by his old army title of nearly twenty years before—corporal.

The characteristic writing in advanced general paralysis, irregular, distorted, full of omissions of letters and words, and finally illegible, may be seen in the textbooks on insanity.

It very rarely happens that the onset and early progress of general paralysis are so sudden and rapid that there is no prodromal period or that it is very short.

The symptoms of well-marked general paralysis include four tolerably distinct types, as follows: (1) The demented and paralytic; (2) the hypochondriacal; (3) with melancholia; (4) with exaltation and mania. There are mixed cases in which some or all of these forms occur. The period of invasion or prodromal period, be it short or long, has, as a rule (not always), gone by when the disease has arrived at a point in its progress to be definitely placed in any or several of these four types.

The demented form of general paralysis is the most common, and is also that in which the greatest increase has been noticed during the last decade, whether from more accurate diagnosis or by reason of an actually greater proportion, probably to a certain extent due to both causes. It consists in a very slowly-advancing mental impairment, making progress side by side with muscular loss of control and power, which may continue several months or years before their importance is appreciated, the vasomotor disturbances not being so marked as in more acute forms of the disease, and the changes in the mental state and bodily strength from week to week being so slight as to escape observation. Attacks of dizziness, petit mal, and epileptiform seizures are quite common in this type of general paralysis. In one of my cases a lawyer in the third year of the disease was retained as counsel in a will case involving over a million dollars, when he fell repeatedly in the streets, and when his occasional, indeed frequent, mental lapses were so apparent to his partners that they did not allow any of his business letters to leave the office without being first inspected by them. Mental excitement, maniacal symptoms, and delusions of grandeur rarely occur, except as transient attacks, until the final stages. The patient commonly realizes that something is the matter with him until he becomes quite demented, and can often describe his

mental state and general symptoms quite intelligently, although rarely with a full appreciation of their extent and import. He easily persuades himself that it is not worth while to take steps for medical treatment, and keeps on with his work until some distinct failure in his mental or physical powers, usually a sense of malaise, muscular pains, a feeling of exhaustion, convinces him and his friends that a physician should be consulted. Perhaps he goes to some health-resort or water-cure, or tries rest and recreation in travel, still thinking his case not an important one, until he seeks medical advice to please his family or friends. He may say that he is only tired mentally and physically.

In the hypochondriacal form of general paralysis, vaso-motor disturbances, flushed or pale face, headache, defective circulation, and various abnormal sensations referred to the peripheral nerves and internal organs are associated with a hypochondriacal mental state, which is also marked by an evident mental impairment, manifested in an almost childish changeability of complaints. Grand delusions and great mental and motor excitement do not, as a rule, appear until the later stages, but the hypochondriacal form is less subacute than the demented.

In general paralysis with melancholia the sad delusions are apt to be associated with some form of expansive ideas or to be transformed into them at some stages of the disease, although the classical delusions of grandeur are a late symptom.

The maniacal form of general paralysis with the *délire de grandeur* is the disease as described by Calmeil. Mental exhalation and delusions of personal importance are its conspicuous features. It may develop at any time in the course of the other three forms just mentioned; its prodromal period may be such as has been described, usually shorter, or the symptoms may be of excitement and maniacal from the beginning. It is the general paralysis of the books until within recent years.

It is doubtful whether these four forms of general paralysis depend upon any pathological basis which can now be determined, but their recognition is practically important for an early diagnosis, and they differ from each other very little in their later and final stages. They constitute what is known as the descending form of general paralysis, in the majority of cases of which descending degeneration of the lateral columns of the spinal cord or posterior spinal sclerosis, or both, appear, secondary to the brain disease.

In the ascending form of general paralysis there are posterior spinal sclerosis and the usual symptoms of that condition—which are described in another article of this work—from one year to a dozen or more years before there are indications of dementia.

In the first stage of general paralysis, although a distinct loss of power is an early symptom, it is not so striking in its manifestations as loss of control. The moral obliquity and the mental lapses seem entirely out of proportion to the general mental impairment. What seems moral perversion is often strictly so, but oftener it depends upon a want of attention or appreciation of the facts in the case, which can be aroused if there is opportunity for it. There is a clear inability to use the force that the mind has. The foolish credulity and readiness to be duped are often only a temporary condition. There is, at the same time, an inability to co-ordinate the muscles to a striking degree at a time when there is still

only slight impairment of the muscular strength, or inversely, and the co-ordinating power may improve up to a certain point, while the muscular impairment goes on. This ataxia is first noticed in those muscles requiring the nicest adjustment for their usual work, the penman's and the pianist's fingers, the proofreader's eyes, the singer's throat. But it may be for a long time very slight or not easily detected.

Although this muscular ataxia may be observed, even if not constantly, in the prodromal period of general paralysis, it is usually well marked only when the symptoms have become well developed. There is also a fibrillary tremor of one group of muscles or of one set of fibres after another when these muscles are exerted, and increasing as they become wearied, as they soon do, from the exercise. The handwriting may show no conspicuous fault at the top of the page, and at the bottom be full of evidences of muscular tremor and unsteadiness, or a single word may be written without conspicuous fault, and a few lines serve to show ataxia of the muscles used in writing. In beginning to read there may be only the most trifling want of clearness of tone and steadiness of articulation, noticeable only to the most practised ear, which after a number of minutes becomes a distinct harshness of voice or evident stumbling over linguals and labials, or hesitation in speech, which may seem like the utterance of a person slightly under the influence of wine or with lips cold from frosty air. The hesitancy of speech is due partly to a slower flow of ideas than in health, an impaired power of attention to the subject in hand, a diminished creative power or expression of thoughts, but also to a distinct ataxia, an inability to promptly co-ordinate the muscles required to perform the act. The difficulty in reading is partly mental and in part due to inco-ordination of the muscles governing the eyes as well as those of articulation.

These muscular defects and mental inefficiencies, when slight, may be hardly detected after the patient has had a prolonged rest and is quiet and calm. After some emotional irritation, weariness, sleeplessness, vaso-motor disturbances, or congestive attacks they become very pronounced. After several weeks of absolute rest, with the patient still at rest, it may be impossible for a time to find any trace of mental defect or muscular deficiency until the patient has again been put to the strain following some effort. They are very much increased after epileptiform or apoplectic attacks, which, however, are uncommon so early in the case.

In the progress of the disease, as the mental impairment increases, the reaction of the nervous system to external conditions becomes less active, the mind weakens, the loss of flesh may be, at least in part, regained, a great portion of the irritability and active symptoms disappears, and as the patient grows worse he may seem for a while to his friends to improve.

The leading symptoms of general paralysis of the insane are—(1) vaso-motor, (2) mental, (3) physical.

The vaso-motor symptoms consist in a progressive paresis or lessened power, which in the progress of the disease advances to complete arterial paralysis—at first a functional disorder of impaired innervation, and finally organic. They are marked early by rapid changes in the cerebral circulation, a diminished arterial tension, with occasional or frequent attacks of vertigo, dizziness, or faintness, confusion and incoherence that may amount to a transient dementia, localized and general elevation or

depression of the bodily temperature ; frequent attacks of congestion or at long intervals, with a flushed face or transient cerebral anæmia, may be marked by sharp emotional disturbances, fits of temper, irritability, maniacal excitement, loss of self-control, etc., or by epileptiform and apoplectiform seizures of various degrees of severity, with or without temporary or transient loss of muscular power, local or of the monoplegic, hemiplegic, or paraplegic nature, of a much less severe character than similar attacks later in the disease, due in part also to organic changes. The circumscribed loss of power of the vessels of the skin leads to various functional disturbances, and finally to paralysis, involving bed-sores, etc. Cyanosis, neuroparalytic hyperæmia of the lungs, bladder, and intestines, cold feet, œdema of the skin, local sweatings, etc. are final evidences of vaso-motor paralysis. Throughout the disease, at least nearly to the end, this vaso-motor paresis and paralysis causes marked variations in the mental state which are too rapid to be accounted for by organic changes.

After there is evidence of definite atrophic and degenerative disease in the brain, as indicated by great mental impairment and muscular paralysis, the mental and physical symptoms may be subject to great changes, without any apparent cause but vaso-motor disturbances, and alternating rapidly from extreme intellectual confusion and absence of mind to a clear, even if temporary, mental state. Less extreme changes in the condition of the mind are common.

The mental symptoms, after the disease is pronounced, consist in an intensification of those already mentioned as characterizing the prodromal period—in an increase in the loss of power of control over all mental operations and in the loss of mental power, the two symptoms making progress side by side. In the form of the disease attended with maniacal excitement the prodromal period is usually shorter than in the others, but may last several years. After the prodromal period has passed the mental impairment increases, so that the judgment, memory, power of attention and expression grow progressively worse ; and this impairment constitutes the only characteristic mental state universally present in all stages of general paralysis of the insane—namely, progressive dementia. The accidental symptoms may be those belonging to any type of insanity except logical systematized delusions. They very rarely simulate the states of mental defect and degeneration.

If there are delusions of persecution, they are marked by a degree of confusion or incoherence not compatible with logical inference. The state of melancholia may change rapidly to mania, and the demented form may at an hour's notice become the excited. Where the symptoms of mental exaltation and depression alternate, resembling *folie circulaire*, the alternation is less regular than in alternating insanity properly speaking ; hallucinations of sight and hearing and of all the special senses are quite common, although, as a rule, rather late symptoms, and then confused and often only partially intelligible. There are also all sorts of illusions and delusions.

The impairment of the sense of right and wrong becomes quite marked ; the patient loses the sense of property and ownership. In no other disease could the reported case occur of a man, to outward appearance well, going up to a policeman and asking his assistance in rolling off a barrel

of liquor which belonged to some one else, and which he meant to appropriate. For this reason what seem to be thefts are very common, and although by that time there is striking mental impairment, it may not be obvious to every-day people. Almost every other moral obliquity occurs, particularly a tendency to drunkenness and every possible violation of the proprieties and laws regarding property and the sexual function. It is all done, too, in such a foolish way that the insanity would be apparent to almost any intelligent person before whom the facts might be fully and clearly placed. There may be a curious consciousness in the patient of the fact that something is the matter with him, and a most extraordinary unconsciousness of what an inordinate fool he is acting. If he can be made to see what folly he is committing, perhaps a few moments later he is saying that he was n-ever b-better in his life. The emotions change most rapidly, and an adroit examiner will have his patient crying over some trifle one moment, and another moment laughing over something equally inconsequent. The prevailing mental state changes as rapidly as the emotions. Violent anger, outbursts of passion, penitence, amusement do not succeed each other more rapidly than indifference, melancholy, and exaltation.

The suicidal idea is common in general paralytics before they become very demented; the suicidal impulse is rarely strong enough to result in anything more than futile attempts at self-destruction. Suicide by deliberation is also rare, for even when it is meditated the weakened, indecisive mind usually fails to prepare adequate plans for its successful issue. Homicidal attempts are not to be expected as a rule, except in the delirium of the states of maniacal excitement or in an outburst of anger for a fancied wrong or deliberately for some trifling reason. Even from suicide and homicide a practised physician or attendant will easily turn the general paralytic who is not maniacal to some amusing or silly thought. He has become credulous, simple-minded, and easily moulded to an expert's wishes, so far as his general conduct is concerned, and yet at any moment he is capable of a furious mania or a violent storm of passion, which after cerebral congestive attacks may be long and severe. Sometimes these symptoms just described may be very pronounced at night and not especially troublesome during the daytime. I have had patients who were dangerous, violent, noisy, deluded at night, and entirely quiet by day, for several months.

The mental state is of progressive impairment. The ideas flow slowly, and there is slowness or hesitation in speech in giving utterance to them, even to the degree of amnesic aphasia. Word-blindness occurs, and word-deafness and the various disturbances of speech associated with the several forms of aphasia. After the dementia is very marked there is often a most extraordinary variation in it. The patient may be confused, incoherent, and to appearance hardly capable of sustained thought, but soon quite able to perform a business transaction. The friends say of such patients, "He is crazy to-day," or "To-day he is sane;" and this quite independent of the marked increase in the dementia which occurs from organic changes, epileptiform and apoplectiform attacks, after which the advance in the mental impairment is rapid and great. Accompanying dizzy and congestive attacks there is a temporary dementia which may be over in an hour or two.

The patient may recall many long-past events fairly well when he cannot find his way to the dinner-table without blundering, when he does not know morning from afternoon, and after he is unable to dress and undress himself without constant reminders or even actual help. Such paralytics wander off and die of exposure, are picked up by the police as having lost their way or as not knowing where their home is, or fall into some fatal danger from which they have not mind enough to extricate themselves. When the mental impairment has reached this point the lack of mind shows itself in a lack of facial expression, which is so characteristic of the disease that with a practised eye it is recognized as far as the countenance can be distinctly seen; and from this point the progress is commonly quite rapid to absolute dementia, entire inability to form or express thoughts, too little intellect to even attend to the daily natural wants, and a descent to the lowest possible plane of vegetative life, and then death.

At some time or other in the history of general paralysis delusions of grandeur, a general feeling of personal expansiveness or extreme self-satisfaction, may be confidently looked for. In the melancholic and hypochondriacal forms of the disease, as has already been mentioned, they are late symptoms; in the demented type they occur only, for the most part, near the final stage of absolute dementia; and in the excited form they are usually found from the beginning or at least developing from a general feeling of *bien-être*. They may vary from what would pass as inordinate, silly conceit to a wildness of delirium which stops hardly short of infinity. The patient is the greatest financier, the handsomest man, the best runner, can out-box the champion pugilist, can write the finest sermons. Delusions of this degree, especially in women, are apt to refer to the reproductive faculty or to the qualities which please the opposite sex. One man can make a million dollars a day writing poetry; another is building cities of solid gold; another owns all the railroads in the country, is king over all the earth, god over God; another is running express-trains over his bridge across the Atlantic or has a doctor who comes to see him in a balloon. There is often a depth of vulgarity and obscenity about the delusions which is rarely seen in other diseases. When the grand delusions appear in the melancholic form, they are apt to be tinged with gloom, as of a queen whose diamonds are withheld from her, a lover who is kept from his princess bride, etc. In the hypochondriacal form it may be a crystal liver, a silver stomach, a brain of solid gold, etc.

Delusions of personal belittlement, called *micromania*, sometimes follow or alternate with the *megalomania*.

Maniacal excitement is a late symptom in the demented, hypochondriacal, and melancholic forms of general paralysis; and it rarely occurs in them except in the final months of the disease, unless as a direct sequence of congestive, epileptiform, or apoplectiform attacks, and then it lasts usually from a few hours to several days. These attacks may occur at any time without any warning whatever, and may be attended with fury or stupor also. As a matter of fact, they are very rare at an early stage except in the excited form of general paralysis, of which they are a pretty constant symptom until marked dementia has appeared, and they may continue to the end. The fury of these maniacal attacks is of the most furious and maddest kind, blind, the most utterly regardless of consequences

of any kind of insane excitement, and without the intelligence even of the acute maniac.

The ability to recognize his own mental state is sometimes retained by the patient, at certain times at least, to a quite late stage in the disease, so that he learns to call his visions hallucinations and his strange fancies delusions. He may even agree that his illusions are all nonsense, that the disease is in his brain. The so-called lucid intervals are not uncommon until the final stage of absolute dementia, when attention, memory, judgment, conception, connection of ideas, imagination, desires, the exercise of the senses, general sensibility, after becoming more and more imperfect are at last completely suspended. The moral sense and finer feelings had gone long before.

Although the story of the mind's decay in general paralysis is a comparatively short one, from a few weeks to four or five years for the prodromal period, and then an average of two or three years for the rest, but varying from a few weeks to a rare extreme of twenty years, there may be at any stage of the disease, except at the very end, a more or less complete remission lasting from a few months to ten years. It is dangerous to say, therefore, that there is any degree of dementia which may not be temporarily at least, or in some part, recovered from. Most of the reported cures of general paralysis have been at last proved to be simply remissions, which may be partial or so complete as to leave no trace to the most practised observer. It is not uncommon to see a remission of six months or a year or two, in which the patient can lead a quiet life; it is seldom that he undertakes responsibilities without bringing the remission rapidly to an end. There are a few cases where active business has been resumed and followed successfully for several years. But there is apt even then to be some deterioration in character, which may amount to an actual moral insanity. An arrest in the downward progress, so that the symptoms remain for a considerable time without essential change, is not very uncommon, and may occur at any stage of the disease.

The physical symptoms of general paralysis consist in impaired control over the muscles, diminished power of co-ordinating them, followed at once by progressive muscular enfeeblement ending in complete paralysis.

The ataxia first shows itself in the finer muscles—of the eye, of the fingers, of articulation. There is a little hesitancy or rather deliberateness of speech, the voice loses its fine quality, the intonation may be slightly nasal. Instead of contracting smoothly and evenly as in health, the muscles show a hardly noticeable jerkiness; an irregular fibrillary tremor is seen when they are exerted to their utmost and held in a state of extreme tension for several moments. In attempts to steady the handwriting the patient forms his letters slowly, makes them larger than usual, or tries to hurry over the letters, making them smaller. The coarser muscles show ataxic symptoms much later. It is observed by the patient or his friends that he does not walk off with his usual rapid gait, and the effort to co-ordinate his muscles produces an early or unusual fatigue, which may be associated with general muscular pain. Extreme soreness and pain, following the course of some one or more of the main nerve-trunks, may be most persistent and obstinate to treatment, lasting for several years, limiting the motion of the limb, some-

times beginning a year or two before other symptoms are observed. Sooner or later, especially after a little weariness or excitement, there are observed at times, not constantly, indistinctness or an occasional trip in enunciating linguals and labials, a tremor in the handwriting, a slight unsteadiness in the gait. When the tongue is protruded as far as possible, when the hands and arms are stretched out, when the muscles of facial expression are exerted, in standing with feet together with closed eyes, a decided muscular tremor and unsteadiness are remarked. These muscular symptoms soon become constant, although they may be so slight as to be well marked only by some unusual test, such as prolonged use after excitement or fatigue, and the ataxia may diminish, the gait, speech, or handwriting may improve, while muscular power is growing progressively less.

In walking the feet are not raised as usual, the steps are shorter, the legs are kept wider apart; turning about is accomplished in a very deliberate way, such as to suggest an insecure feeling; movements like dancing are impossible. Going up and down stairs is difficult; the whole foot is rested carefully on each step, and the head and shoulders are held stiffly, so as to maintain the balance. The muscular movements are generally uneven and tremulous, and yet the strength may not be so very much impaired, although perhaps available only for short periods at a time. Even these symptoms may so improve by a few days' quiet, or even by a night's rest, as to quite throw the physician off his guard unless a thorough examination is made. The patient, too, on an even floor or sidewalk may walk so as not to attract attention, and yet in a new place, over a rough surface, or in the attempt to perform difficult or rapid movements, exhibit striking ataxia and feebleness of gait. In starting off with a definite purpose he may for a short distance walk quite well, as he may do under the influence of a glass of wine.

From this point the progress is usually rapid. The handwriting becomes more and more tremulous, unsteady, full of omissions of letters and words, disjointed, disconnected, and finally illegible; the articulation more thick, stammering, hesitating, indistinct, unintelligible; the gait staggering, shuffling, straddling, uncertain, unsteady, even to causing frequent falls. There may be still a considerable degree of strength for a single short effort, but the co-ordination is so imperfect as to make it avail little. The voice, for instance, may be loud and forcible, but the co-ordination sufficient for only a short explosive utterance of one syllable, and then quite an interval before the force can be concentrated for the next. Progressive muscular paresis becomes finally absolute paralysis.

Remissions in the physical symptoms follow the same general laws as in the mental symptoms, but are not so complete, and there may be an arrest in their progress also.

In all stages of the disease, especially the later, there may be almost any of the symptoms observed which occur in the various functional and organic diseases of the nervous system. The hyperæsthesia, local or general, may be most absolute, or the anæsthesia so complete that acts of self-mutilation ordinarily causing exquisite pain are performed without apparent suffering. Any motor ganglia, any nerve, any tissue, may degenerate, giving rise to various degrees of impairment up to total

destruction of function—of the optic nerve, causing blindness; of the auditory, deafness; of the olfactory, glosso-pharyngeal, or any of the cranial or spinal nerves.

The pupils may be of normal size. They may be of normal or sluggish accommodation to light and distance, or there may be dilatation or contraction of either or both pupils and no response to light or accommodation. The pinhole pupil is not uncommon. There may be neuro-retinitis, atrophy of the disc, neuritis, nystagmus, diplopia, amblyopia, hemianopsia, color-blindness, ptosis, conjugate deviation of both eyes, or paralysis of any of the ocular muscles. The paralysis of one of the muscles of the eyeball may be one of the earliest and most persistent symptoms. The optic neuritis or atrophy may also occur early, but seldom appears in time to aid in a doubtful diagnosis.

Sugar has in a few cases been found in the urine; albumen is not uncommon.

The sexual function is commonly exaggerated in the early stages, then diminished, lost, and finally returns in the stage of absolute loss of self-respect and self-control, although it may be impaired from the beginning or not materially changed at first. There may be temporary or persistent incontinence or retention of urine.

At first there is a marked loss of flesh, then a gain. As the muscles lose in power they increase in size, with an interstitial degeneration. The deposit of fat is sometimes enormous. In the final stage there is emaciation.

The convulsive attacks usually are of the nature of cortical epilepsy, or at least commonly begin as such. They are associated with and followed by a considerable rise in temperature—from two to seven degrees F.—and are immediately succeeded by marked increase in the severity of the symptoms, both mental and physical, especially if the attacks follow each other in rapid succession or last for a number of days. They may be due to hemorrhage, embolism, or effusion, and be marked by any or all of the usual symptoms and sequences of those conditions, permanent or transient. General and aural vertigo are not uncommon.

The muscular tremor before the last stages varies in different muscles—excessive perhaps in the tongue, moderate in the fingers, and so on. It may also seem slight as compared with the other symptoms, or, on the other hand, be enormously exaggerated in certain groups of muscles out of all proportion to all other indications. At the end extreme and constant tremulousness accompanies every voluntary movement.

Spastic paralysis, muscular tension, contractures, rigidity of the most persistent character seem at times to be under the influence of the will, although of cortical origin and in a certain sense automatic, like convulsions.

The knee-jerk is changed in somewhat more than half the cases, a little oftener exaggerated than abolished; but sometimes the reflexes are enormously increased all over the body, so that a strong puff of air in the face even will set the arms and legs going like a jumping-jack. I have twice seen the patellar reflex abolished in one leg, and so marked in the other as to seem to me exaggerated.¹ I have also known it to disappear

¹ There was no evidence, and there had been no history, of a hemiplegic attack in either case.

absolutely in both legs two weeks after it had been found to be excessively exaggerated. It also varies under conditions of rest, fatigue, excitement, etc. Intense pain in the joints occurs, and I have found it where the knee-jerk was exaggerated, in one case giving rise in a physician to the delusion that his arms and elbows had been resected. This may disappear in time. Charcot's joint disease has been observed.

In the final stages the bones are fragile and easily break; hemorrhages under the periosteum or perichondrium arise from trifling force or injury, giving rise to hæmatomata, the most common of which are on parts exposed to pressure, etc., as the ear. The patient is confined to his bed, fed like a small child, demented, hardly able to articulate the extravagant delusions which form such a grotesque contrast to his actual state, until the mind is as incapable of forming or receiving ideas as of expressing thoughts; and the body is simply a filthy, helpless mass of humanity, dying of exhaustion or decay, unless lung gangrene, bed-sores superficial and deep, necrobiosis, exhausting diarrhoea, pneumonia, pulmonary consumption, perhaps asphyxia from an epileptic fit or choking, have followed incontinence of urine and feces to the fatal end, or heart failure or apoplexy have closed the scene.

PATHOLOGY AND MORBID ANATOMY.¹—General paralysis of the insane is, according to Mendel, following Rokitansky's idea, a connective-tissue disease, affecting the nerve-cells and tissues secondarily, while Tuczek and Wernicke think that the primary disease is of the nerve-elements (*primäre Atrophie der Nervelemente*)—a diffuse interstitial cortical encephalitis on the one hand, or a diffuse parenchymatous cortical encephalitis on the other. There is also, in well-marked cases, atrophy of the white substance, due, according to general opinion of pathologists, to primary interstitial encephalitis ending in sclerosis.

In the majority of cases there is pachymeningitis, often extensive and excessive, with hemorrhages, but which may be no more than is quite commonly found in persons dying of phthisis or chronic nephritis. There is also, usually, leptomeningitis, with adhesions to the cortex, especially of the anterior and antero-lateral portions, so firm that the arachnoid cannot be removed without tearing off portions of the brain; but it is sometimes scarcely observed, and may be no more than is found in persons dying simply of old age. The pia may be in places thickened, opaque, and without adhesions. Ependymitis is usual.

In the terminal stage of general paralysis there is well-marked atrophy (with compensatory serous effusion), which is, as a rule, most marked in the cortex of the brain, but which is of varying degrees in its different

¹ For a detailed statement of the post-mortem appearances in general paralysis compare Spitzka's *Insanity*, pp. 218-243; *Beiträge zur pathologischen Anatomie und zur Pathologie der Dementia Paralytica*, von Dr. Franz Tuczek; *Die Progressive Paralyse der Irren*, von Dr. E. Mendel; *Lehrbuch der Gehirnkrankheiten*, von Dr. C. Wernicke, iii. pp. 536-541. Westphal's classical work is not referred to, as his latest views and others of interest are given in a report of a discussion by the German Association of Alienists in the *Allgemeine Zeitschrift für Psychiatrie*, iv. 1883, pp. 634-638 and 648-654. In the third number of the *Neurol. Centralblatt*, Mendel reports an autopsy of a patient diagnosed to have melancholia, who died a violent death, where he thought that he found evidence of the early stage of general paralysis in moderate opacity of the pia mater, with nodules as large as a pin's head in both parietal regions, and in slight indications of diffuse interstitial inflammation of the cortex, the blood-vessels in the frontal convolutions being extensively filled with white blood-corpuscles.

portions. Rarely there is scarcely any atrophy of the cortex. The central portion of the brain may be of leathery consistence, but usually shows marked sclerosis, which also may affect its different portions and the different ganglia very differently. The changes resulting from inflammatory, degenerative, and atrophic processes are general and profound.

An opinion is beginning to obtain that general paralysis is primarily a disease of the small cerebral blood-vessels, functional or vaso-motor; and Meynert holds that the transition line between that stage, which he considers curable, and organic disease may be recognized clinically.

In general paralysis, as in other mental diseases, the nervous discharge is accompanied by a greater disturbance in the structure of the gray substance of the brain, a more extensive decomposing of it, and consequently by a more complete exhaustion of nervous force than in healthy mental processes. Longer periods of rest and improved nutrition are therefore necessary to restore healthy function. In general paralysis, as in all other mental diseases dependent upon destructive disease of the brain, there is not only decomposing, but decomposing and disintegrating, of the structure of the brain.

Posterior spinal sclerosis is frequently found. If alone or predominating over sclerosis of the lateral columns of the cord, the knee-jerk is abolished if the morbid process has gone far enough. If descending degeneration of the lateral columns is chiefly found, and is sufficiently advanced, the knee-jerk is increased. At least one of these forms of sclerosis exists in the vast majority of cases.

There is also a distinctly syphilitic disease of the smaller cerebral arteries, together with a diffuse parenchymatous and interstitial encephalitis of syphilitic origin. At present we have no means of differentiating it at the autopsy from general paralysis following a subacute or chronic course, except inferentially from the presence of other evidences of syphilis. It is not always possible, therefore, to distinguish between syphilis and a syphilitic diathesis as the chief factor in diffuse encephalitis.

DIAGNOSIS.—Although a well-marked case of general paralysis is unmistakable, the diagnosis in the early stages or in obscure cases may be extremely difficult. The varying degrees in which the various portions of the cortex, medullary portion, and different ganglia of the brain may be involved in the morbid process naturally give rise to a great variety in the symptoms, mental and physical, sensory and motor, emotional and intellectual, and in the relative preponderance of one or another in individual cases. The usual symptoms of any form of mental disease may for a time obscure the dementia which sooner or later must appear in general paralysis, and which, as has already been said, is the only mental symptom universally present in all cases. This mental impairment must also be associated with progressive muscular loss of power, although the relation of the two symptoms to each other, the degree to which a given amount of the one leads to a fair inference of a certain amount of the other, is liable to the greatest variation, the range of which can only be learned by observation and experience. There is a certain quality to the dementia, as already described, which is often sufficient of itself to establish the diagnosis with a practised physician.

The early mental symptoms may simulate those of cerebral neurasthenia, in which the patient thinks that there is decided mental impairment, although there is no progressive dementia. The tremor in neurasthenia is greater and more universal than in the stage of general paralysis with which it might be confounded, and the subjective symptoms are much more prominent.

Muscular malaise and pains throughout the body give rise to the diagnosis of malaria or rheumatism, in which there may be loss of power, but no ataxia or dementia.

The sclerosis may be predominating or pronounced in the basal ganglia and bulbar nuclei, giving occasion for a hasty diagnosis of labio-glossopharyngeal paralysis, until it is found that the clinical history of that disease is not followed. In the same way, any motor or sensory ganglia or nerve-roots may be so early implicated in the degenerative process as to mislead the physician into giving attention to only the local symptoms.

Once I have known the early convulsions of general paralysis in a very self-conscious woman mistaken for hysteria, the mental impairment and physical weakness having been overlooked on account of the prominence of the convulsive attacks and the hysterical symptoms, which may be a complication of any form of insanity in young and middle-aged people, particularly women.

It is not uncommon for the attacks to so thoroughly resemble epilepsy as to be mistaken for it, the dementia not being observed or being supposed to be the ordinary mental deterioration generally following epilepsy. In such cases the progressive dementia, ataxia, and muscular weakness may advance so slowly as to entirely escape observation for a long time, and give rise to the confident diagnosis of epilepsy for five or six years. Epilepsy, however, arising in a vigorous, middle-aged person without evident cause, should always suggest the suspicion of syphilis, cerebral tumor, or general paralysis, when careful scrutiny of all the symptoms will show where it belongs.

Embolisms, hemorrhages, cerebral effusions, more or less diffuse encephalitis from an injury to the head, sometimes give rise to the suspicion of general paralysis, until it is found that its characteristic progressive symptoms do not appear, but chiefly when the history of the case has not been definitely ascertained, or when the usual symptoms of those conditions are not well marked.

Chronic endarteritis, arterio-sclerosis, atheroma of the cerebral arteries may be so diffused as to simulate general paralysis, especially in drunkards and syphilitics, but the symptoms do not advance in the manner characteristic of that disease.

Multiple cerebro-spinal sclerosis of the descending form may be confounded with general paralysis while the symptoms are obscure and consist in change of character, when, indeed, organic disease can only be suspected to be present.

Lead has been known to attack the central nervous system in such a way as to produce an intellectual apathy and muscular weakness somewhat resembling the early stage of the demented form of general paralysis, but without its ataxic symptoms and its regular progress. The presence of lead in the urine, and the marked improvement from the use of

iodide of potassium, tonics, and electricity, are sufficient to establish the diagnosis.

Chronic and persistent alcoholism is always attended with some mental impairment, which may so resemble the dementia of general paralysis, with marked moral perversion, mental exaltation, grand delusions, muscular tremor, ataxic symptoms, and impaired muscular power, as to make the diagnosis doubtful for several months, until removal of the cause (alcohol) in the course of time causes the symptoms to so abate as to make the real character of the disease evident.

I have once seen chronic interstitial nephritis without its usual prominent symptoms and with mild uræmic convulsions mistaken for general paralysis.

A tumor of the brain, if not attended with the common symptom of vomiting, may be the cause of convulsions and headache resembling those often seen in general paralysis. Optic neuritis or atrophy is usual in cerebral tumor, but rare in a stage of general paralysis so early that the diagnosis might be doubtful.

Hemorrhagic pachymeningitis also now and then simulates an obscure case of general paralysis in the early stage, but a few weeks at most settle any doubts in the matter.

Although diffuse cerebral syphilis is more apt to be associated with distinctly localized symptoms than the demented form of general paralysis, and although it is characterized by a mental apathy and physical torpor which follow a more regular course with more definite symptoms, resulting in a slow decay, yet there may be doubtful cases in which the differential diagnosis is impossible, and in which antisyphilitic treatment does not throw any light on the subject. Syphilitic new growths, endarteritis, and meningitis may so far improve from the use of mercury or the iodide of potassium as to end in an apparent cure, but in those cases the symptoms are not so marked as to make an exact diagnosis always possible. A distinct syphilitic cachexia is presumptive evidence of syphilitic encephalitis when there is doubt whether the syphilis is the cause or the diathesis.

Profound melancholia is not so often as varying gloom or moderate despondency a symptom of general paralysis. When it is such, there are developed in time the other marks of that disease, and it will only be necessary to hold the diagnosis in reserve for their appearance. The melancholia masks the dementia unless it is very carefully sought for, and the tremor may be as marked in melancholia as in the early stage of general paralysis, but more universal.

Acute mania is not uncommonly mistaken for general paralysis, when, as often happens, the delusions are as expansive and the tremor as great in the mania as in general paralysis; and it may be several months before the differential diagnosis can be made with certainty. In the presence of a high degree of maniacal excitement, with great emotional agitation and muscular tremor, it is difficult to establish the fact of the existence or not of dementia in doubtful cases until it is well developed. Acute mania has been known to constitute the prodromal period of general paralysis for a number of years.

Primary mental deterioration cannot be always differentiated from general paralysis of the demented type in its early stage. After the

age of sixty the probabilities are in favor of primary mental deterioration in doubtful cases, but general paralysis occurs—seldom, to be sure—up to the age of sixty-five.

Early senile dementia may simulate general paralysis of the subacute form, but has not its clinical history. General paralysis of the quiet, insidious type and primary mental deterioration have been called premature senility. The three diseased conditions have certain points of similarity, and the pathological processes involved in them do not differ sufficiently to authorize the assumption that they are not closely related, if not simply variations, due to age and other causes, in one morbid process.

Finally, the mental impairment caused by the prolonged use of bromide of potassium and hydrate of chloral has been mistaken for general paralysis, until a critical examination unmistakably showed the presence of the well-known symptoms of those drugs.

In examining the patient it is especially important to avoid leading questions, as in general paralysis and in those conditions which simulate its early stage the mind is in a condition to readily fall into the train of thought suggested to it. The fact should be kept in mind, too, that the symptoms in early general paralysis are so variable as to be sometimes quite evident, and at other times not to be got at with certainty at all or only after long and patient examination; that they sometimes quite disappear under the influence of complete mental and bodily rest; and that in all stages, until near the end, such complete remissions may occur as to make the diagnosis, independent of the history of the case, difficult if not impossible.

A gentleman once committed an offence characteristic of general paralysis in marrying a pretty servant-girl while temporarily away from his home. His wife, daughters, and friends saw that the act was so contrary to his natural character that he was placed in an insane asylum and kept there several weeks under observation for an opinion as to his responsibility. He appeared so well in the absolute quiet and rest that he was declared sane, tried, and sentenced to the State prison, where he showed his marked mental impairment as soon as he was set to work. He could not concentrate his mind sufficiently for the simplest labor, and a couple of years later he was sent to the insane asylum to die, a complete mental and physical wreck, in the late stage of general paralysis.

PROGNOSIS.—The very few reported cures in so common a disease as general paralysis, and the circumstances under which they have been reported, lead to the suspicion that there was an error in diagnosis or that the mistake was made of supposing a remission to be a cure, as has often happened. The course of the disease is more rapid in men than women, and in young persons than in the older. From the galloping cases of a couple of months to those slowly advancing, with long remissions, over twenty years, the average, including the prodromal period, is probably not far from five (perhaps six) years. Collected from asylum statistics, it is given as from two to three years. When I am sure of the diagnosis, I generally say that the patient may die within twenty-four hours (of paralysis of the heart, from suffocation by an accident in an epileptic attack, from choking, from cerebral hemorrhage or effusion, or suddenly with cerebral symptoms of which the autopsy gives no satisfac-

tory explanation), within a short time of intercurrent disease, especially diarrhœa or pneumonia, or that he may live several years, as he probably will, and possibly have a remission, during which he may lead for a while somewhat the same kind of life as other people.

Persons presenting symptoms which can in no way be positively distinguished from those at the beginning of the prodromal period of general paralysis recover, but not many come under the physician's care so early. We are not yet in a position to say whether they were suffering from a mild, transient illness or from what would otherwise have become serious organic disease.

TREATMENT.—Life may be prolonged in general paralysis, and usually is prolonged, by the use of such measures as contribute to the patient's comfort, and which in a general way have already been considered under the head of treatment of mental disease on a previous page.

In my experience, stimulating tonics, wine, and even coffee, increase the morbid cerebral energy of the early stage of the disease, but are sometimes of use later. Cod-liver oil and the hypophosphites do better, and many of the disagreeable symptoms of the period of loss of control over the involuntary muscles are relieved by strychnia. Ergot and the judicious use of the bromides abate the cerebral congestion. Gastro-intestinal disorders, when not controlled by attention to diet, require the usual treatment.

Iodide of potassium in the large or small dose, and mercury, I have never found to benefit those cases of general paralysis with a previous history of syphilis. On the contrary, they have proved debilitating and harmful.

When furious excitement is not relieved by prolonged warm baths, with cool applications to the head if possible, and quiet, chloral is of use, and sometimes opium and its preparations.

Frequently-repeated violent convulsions, the epileptic state, are usually at once mitigated by chloral given by the rectum; the inhalation of nitrite of amyl is reported also to have been of use.

There are few cases in which I find that morphine does not quiet restlessness, calm delusions, abate distressing hallucinations, and make the patient generally more comfortable; and I give it freely, seldom more than twice a day, often almost daily, for two or three years. In this way it can be used in quite moderate doses. Coca also relieves symptoms.

Rest and quiet are most important in all stages of the disease. This can be best accomplished in a quiet private house in the country, which can be made a virtual hospital, and next in a private asylum. But such care is beyond the reach of the vast majority of the insane, to whom the public asylum becomes a necessity. Wherever they are, an orderly life is best for them, with as little irritating interference with their ways or control of them as is possible.

If the results of treatment are in the highest degree unsatisfactory, and consist chiefly in meeting symptoms as they come up, without hope of permanent recovery, it is not impossible that when we can put the patient under treatment at the very beginning of his disease, as we can now do in pulmonary consumption, the prognosis in the former disease may change as much for the better as it has changed in the latter.

A general paralytic is at any time liable to congestive or maniacal

attacks of short duration, and so is always, potentially, a dangerous person. In the prodromal period the risk is small; in all stages there will, in the majority of cases, be some warning; but in the developed disease the only safe way is to have some responsible person near at hand, both to prevent the patient from doing harm to others and to save him from injuring himself, whether by intent or through not knowing better than to wander off or fall into all sorts of accidents. In many conditions several should be readily available, or else the security of an asylum must be sought.

In the treatment of general paralysis by society the same rule should obtain as in all forms of insanity—that distinct mental disease is presumptive proof of irresponsibility, or at least of limited responsibility; that a diseased mind means lessened intellectual power throughout and diminished ability to choose the right and avoid the wrong; that there are changes in circulation or nutrition, or some unknown condition in the brain, especially in general paralysis, by virtue of which the mental state and power of self-control vary from time to time, and as a result of which a person seeming responsible one day may have been quite irresponsible some previous day.

INSANITY FROM GROSS LESIONS OF THE BRAIN (tumors, new growths of all kinds, exostoses, spicules or portions of depressed bone, embolisms, hemorrhages, wounds, injuries, cysticerci, etc.) is attended with the usual indications of those conditions which may determine diffuse disorders of the brain, giving rise to any of the symptoms of the various psychoneuroses and cerebro-psychoses. The lowered mental and moral tone after cerebral hemorrhages is a matter of common observation, and after one an individual is rarely observed to be fully himself again.

The PROGNOSIS is very unfavorable. Although there are rare cases of improvement, the tendency is toward profound dementia.

CEREBRAL SYPHILITIC INSANITY comes either under the head of the insanity last described or belongs to the slowly-advancing dementia with final paralysis already referred to under the head of Diagnosis in General Paralysis, and called by some authorities on mental disease pseudo-paralytic dementia from syphilis.

Antisymphilitic treatment is of value in the first class of cases, and although most of the recoveries end in relapses and incurability, the prolonged use of iodide of potassium seems sometimes to effect a permanent cure. It is claimed that similar treatment is followed by the same result in the cases of dementia with paresis, but the weight of authority, and certainly my own experience, are against that statement.

CHRONIC ALCOHOLIC INSANITY depends upon the vascular and other changes due to abuse of alcohol so long continued that the pathological condition has become organic and incurable. It is commonly associated with delusions of suspicion or persecution. It may be a purely moral insanity, with gross beliefs rather than distinctly insane delusions, and it rarely fails to be at least that when the persistent excessive drinking is kept up until the age of beginning dissolution of the brain. It then gives rise to all sorts of embarrassing complications in regard to property, family relations, and wills. Chronic alcoholic insanity may take the form of mild dementia, by virtue of which the patient cannot control himself, but can be easily kept within bounds of reasonable conduct by various degrees of restraint, from the constant presence of a responsible

person to the seclusion of an asylum. In well-marked cases this dementia is associated with muscular weakness, tremor, and exhilaration to such an extent as to simulate general paralysis. It is then called by some—especially French—writers pseudo-paralytic dementia from alcohol.

The condition is susceptible of improvement by removal of the cause, alcohol, and by a carefully-regulated life, hydropathic treatment, etc., but complete recoveries cannot be expected.

SECONDARY DELUSIONAL INSANITY is slowly developed from various mental diseases, incurable or uncured, where the progress to marked dementia is slow, by the persistence of delusions in those forms of insanity characterized by delusions. It is chronic and incurable. In melancholia and mania the mental depression and the exaltation and motor excitement disappear to a great extent, and there are left a slowly-advancing dementia, confusion, and expanding delusions, with apathy or with agitation, for which the asylum is the only safe place unless physical weakness makes the patient harmless. It is either a terminal state in which many forms of insanity end, or a stage through which they pass to terminal dementia. It depends upon incurable, and therefore organic, changes in the brain, like all incurable insanity, although those changes are not yet determined exactly. It might be a question whether chronic delusional insanity properly belongs under the head of Organic Mental Diseases, and a similar criticism may be made regarding terminal dementia. But in this paper no definite classification of insanity is attempted, because our knowledge of the subject is still so indefinite, although the several mental diseases are grouped in a certain order for convenience to the reader and the writer; and this order of course approximately follows natural lines.

TERMINAL DEMENTIA is the end to which most of the insanity not resulting in recovery finally comes. The features marking the disease in its early stages for the most part disappear, leaving all the functions of the mind impaired in all degrees up to total extinction—the whole character on a lower plane. It is the disease which to so great an extent crowds the wards of insane asylums and almshouses with the (1) agitated or (2) apathetic chronic insane, the worst of whom are mental and physical wrecks, squatting on floors, uttering an unintelligible jargon, noisy, filthy, without intelligence for the simplest natural wants. Their chief function, under the prevalent methods of construction and management of lunatic hospitals in most places, is to blight with a certain feeling of hopelessness many of the curable insane who are obliged to go for rest and quiet to institutions where the overwhelming majority of the inmates are manifestly and painfully incurable.

French writers include a great part of chronic delusional insanity (secondary confusional insanity, Wahnsinn, secundäre Verrücktheit) and terminal dementia (Blödsinn) under one head, *démence*; and with much reason, as it is not always possible to differentiate between the two.

The proper TREATMENT of the incurable, demented insane should provide not only that they be not at large, where they annoy the strong and the well, but also that they shall not disturb the insane who are acutely ill and in need of treatment suited to sick people, and whose chances of recovery at best are none too favorable. Experiments, now quite numerous, have shown that the lives and occupations of many of them may be

made not entirely unlike those to which they were reared, and that nearly all may be suitably provided for without the expensive hospitals and appliances necessary for the proper treatment of acute mental disease.

A comparison of countries in which there is and is not a comprehensive system of State supervision of the insane by a competent board seems to me to reveal so unquestionably the fact that such a system alone provides the proper protection for the insane, and the needed variety and uniformly high standard of excellence in the provisions for their treatment, that I hope to see the medical profession using its vast influence upon public opinion to secure it.

If we meet in the wards of our insane asylums hopeless mental and physical wrecks, if we find there the extremity of human wretchedness, the supreme control of all that is evil or vile in our nature, the worst antitypes of all the virtues, so, on the other hand, nowhere else do we see such struggles for the mastery of the better impulses, such efforts against such odds to hold back the mind in an unequal fight. Nowhere else, too, are developed finer sympathy, more beautiful unselfishness, more generous charity, or more heroic resignation where no hope in life remains but for death.

The State has taken charge of these most unfortunate people, shutting up behind the same locked doors and barred windows people of all social grades, often mingling together in one presence the so-called criminal insane, insane criminals, idiots, imbeciles, epileptics, paralytics, the chronic insane, and the demented, with patients suffering from acute mental disease. Some of them are unconscious of their condition, many are better off than ever before, but others are painfully alive to their situation and surroundings, fully aware of the gravity of their illness, keenly sensitive to the distressing sights and associations, disturbed by the noises, and discouraged by the many chances of becoming like the worst incurables around them. The State cannot evade the responsibility of seeing that their confinement is made the least rigorous, wretched, and injurious possible.

HYSTERIA.

By CHARLES K. MILLS, M. D.

DEFINITION.—Hysteria is a functional disease of the cerebro-spinal axis, characterized either by special mental symptoms or by motor, sensory, vaso-motor, or visceral disorders related in varying degree to abnormal psychical conditions.

This, like all other definitions of hysteria, is imperfect. No absolutely satisfactory definition can well be given. It is not abnormal ideation, although this is so often prominent; it is not emotional exaltation, although this may be a striking element; it is not perversion of reflexes and of sensation, although these may be present. Some would make it a disease of the womb, others an affection of the ovaries; some regard it as of spinal, others as of cerebral origin; some hold it to be a disease of the nerves, others claim that it is a true psychosis; but none of these views can be sustained.

Sir James Paget¹ says of hysterical patients that they are as those who are color-blind. They say, "I cannot;" it looks like "I will not," but it is "I cannot will." Although, however, much of the nature of hysteria is made clear in this explanation, hysteria is not simply paralysis of the will. A true aboulomania or paralysis of the will occurs in non-hysterical patients, male and female, and of late years has been studied by alienists.

In many definitions the presence of a spasmodic seizure or paroxysm is made the central and essential feature; but, although convulsions so frequently occur, typical hysterical cases pass through the whole course of the disorder without suffering from spasm of any kind.

In a general neurosis a definition, well considered, should serve the purpose of controlling and guiding, to a large extent at least, the discussion of the subject.

The definition given asserts that hysteria is a functional disease. In the present state of knowledge this is the only ground that can be taken. It is claimed that in a strict sense no disease can be regarded as functional; but it is practically necessary to use such terms as functional in reference to affections in which disordered action without recognizable permanent alteration of structure is present. Temporary anatomical changes must sometimes be present in hysteria; organic disease may be a complication in special cases; post-mortem appearances may occasion-

¹"Clinical Lecture on the Nervous Mimicry of Organic Diseases," *Lancet* for October, November, and December, 1873.

ally be found as accidents or coincidences; it is possible that structural alterations may result from hysteria; but no pathologist has as yet shown the existence of a special morbid anatomy underlying as a permanent basis the hysterical condition.

The mental, motor, sensory, and other phenomena of hysteria cannot be explained except by regarding the cerebro-spinal nervous system as the starting-point or active agency in their production.

The term vaso-motor is used in a broad sense to include not only peripheral vascular disturbances, but also cardiac, respiratory, secretory, and excretory affections of varying type. Some of these disorders are also visceral, but under visceral affections are also included such hysterical phenomena as abdominal phantom tumors, hysterical tympanites, and the like.

That all hysterical phenomena are related in varying degree to abnormal psychical conditions may perhaps, at first sight, be regarded as open to dispute and grave doubt. It is questionable whether in every case of hysteria the relation of the symptoms to psychical states could be easily demonstrated. I certainly do not look upon every hysterical patient as a case of insanity in the technical sense, but hold that a psychical element is or has been present, even when the manifestations of the disorder are pre-eminently physical. James Hendrie Lloyd,¹ in a valuable paper, has ably sustained this position, one which has been held by others, although seldom, if ever, so clearly defined as by this writer.

The alleged uterine origin of hysteria has been entirely disregarded in the definition. This has been done intentionally. It is high time for the medical profession to throw off the thralldom of this ancient view. The truth is, as asserted by Chambers,² that hysteria "has no more to do with the organs of reproduction than with any other of the female body; and it is no truer to say that women are hysterical because they have wombs, than that men are gouty because they have beards."

SYNONYMS.—Hysterics, Vapors. Many Latin and other synonyms have been used for hysteria: most of these have reference to the supposed uterine origin of the disease, as, for instance, *Uteri adscensus*, *Asthma uteri*, *Vapores uterini*, *Passio hysterica*, *Strangulatio uterina seu Vulvæ*. Some French synonyms are *Maladie imaginaire*, *Entrangement*, and *Maux ou attaques de nerfs*. Other French synonyms besides these have been used; most of them are translations from the Latin, having reference also to the uterine hypothesis. In our language it is rare to have any other single word used as a synonym for hysteria. Sir James Paget³ introduced the term *neuromimesis*, or nervous mimicry, and suggested that it be substituted for hysteria, and *neuromimetic* for hysterical. *Neuromimesis* is, however, not a true synonym. Many cases of hysteria are cases of *neuromimesis*, but they are not all of this character. Among the desperate attempts which have been made to originate a new name for hysteria one perhaps worthy of passing notice is that of Metcalfe Johnson,⁴ who proposes to substitute the term *ganglionism*, as giving a clue to the pathology of hysteria. His main idea is that

¹ "Hysteria: A Study in Psychology," *Journal of Nervous and Mental Disease*, vol. x., No. 4, October, 1883.

³ *Op. cit.*

hysteria exhibits a train of symptoms which are almost always referable to the sympathetic or ganglionic nervous system. This is another of those half truths which have misled so many. The term hysteria, from the Greek *ὑστέρα*, the uterus, although attacked and belabored, has come to stay; it is folly to attempt to banish it.

METHOD OF DISCUSSING THE SUBJECT.—It is hard to decide upon the best method of discussing the subject of hysteria. One difficulty is that connected with the question whether certain affections should be considered as independent disorders or under some subdivisions of the general topic of hysteria. Certain great phases of hysteria are represented by hysterio-epilepsy, catalepsy, ecstasy, etc.; but it will best serve practical ends to treat of these in separate articles. They have distinctive clinical features, and are capable of special definition and discussion.

HISTORY AND LITERATURE.—To give a complete history of hysteria it would be necessary to traverse the story of medicine from the time of Hippocrates to the present. A complete bibliography would require an immense volume. Volume vi. of the *Index Catalogue of the Library of the Surgeon-General's Office, United States Army*, which has appeared during the present year (1885), contains a bibliography of nearly seventeen double-column pages, most of it in the finest type. The references are to 318 books and 914 journals. The number of books and articles cited as having appeared in different languages is as follows: Latin, 99; Greek, 2; German, 180; British, 177; American, 159; French, 449; Italian, 75; Spanish, 45; Swedish, 12; miscellaneous, 34. Even this wonderful list probably only represents a tithe of the works written on this subject. Those desirous of studying it from a bibliographical point of view can do so by consulting this great work.

Many as are the names and voluminous as is the literature, certain names and certain works are pre-eminent—Sydenham, Laycock, and Skey in England; Tissot, Briquet, Charcot, and Landouzy in France; Stahl, Frank, Eulenburg, and Jolly in Germany; and in America, Weir Mitchell. The greatest work on hysteria is the treatise of Briquet.¹

Mitchell² has organized into a scientific system a valuable method of treating hysteria, and has given to the world a series of studies of some types of the affection best or only seen in the United States.

Among other American monographs on hysteria and allied subjects worthy of note are the contributions of Shaffer on *The Hysterical Element in Orthopædic Surgery*;³ Seguin's essay on *Hysterical Symptoms in Organic Nervous Affections*;⁴ Beard's volume on *Nervous Exhaustion*;⁵ the chapters on *Hysterical Insanity, etc.* in Hammond's text-books;⁶ and the papers of G. L. Walton⁷ on *Hystero-epilepsy*. Spitzka, Mann, Hughes, and

Kiernan have made important contributions to the psychical aspects of the subject in various American medical journals.

During the last five years I have published a number of articles and lectures on the subject of hysteria and hystero-epilepsy, some of which have been freely used in the preparation of this and the succeeding sections.¹ My first paper on hystero-epilepsy, in the *American Journal of the Medical Sciences*, was written to strongly direct the attention of the American profession to the subject as studied in France. It was in large part a translation from the works of Charcot, Richer, and Bourneville, with, however, notes of some observed cases.

PATHOLOGY.—Strictly speaking, hysteria cannot be regarded as having a morbid anatomy. In an often-quoted case of Charcot's,² an old hystero-epileptic woman, affected for ten years with hysterical contracture of all the limbs, sclerosis of the lateral columns was found after death. On several occasions this woman experienced temporary remissions of the contracture, but after a last seizure it became permanent. This is one of the few reported cases showing organic lesion; and this was doubtless secondary or a complication. In a typical case of hystero-epilepsy at the Philadelphia Hospital, a report of which was made by Dr. J. Guiteras,³ the patient, a young woman, died subsequently while in my wards. Autopsy and microscopical examination revealed an irregularly diffused sclerosis, chiefly occupying the parieto-occipital region of both cerebral hemispheres. Undoubtedly, as suggested by Charcot, in some of the grave forms of hysteria either the brain or spinal cord is the seat of temporary modification, which in time may give place to permanent material changes. Old cases of chronic hysteria in all probability may develop a secondary degeneration of the cerebro-spinal nerve-tracts, or even degeneration of the nerve-centres themselves may possibly sometimes occur. Two cases now and for a long time under observation further indicate the truth of this position. One, which has been reported both by H. C. Wood⁴ and myself,⁵ is a case of hysterical rhythmical chorea in a young woman. Although the hysterical nature of her original trouble cannot be doubted, she now has contractures of all the extremities, which seem to have an organic basis. The other patient is a woman who has

reached middle life; she has several times temporarily recovered from what was diagnosed as hysterical paraplegia, in one instance the recovery lasting for months. Now, after more than four years, she has not recovered from her last relapse. Contractures, chiefly in the form of flexure, have developed, and she has every appearance of organic trouble, probably sclerosis or secondary degeneration of the lateral columns.

Briquet¹ reviews the various hypotheses which have been held as to the pathological anatomy of hysteria, giving a valuable summary of the autopsies upon supposed hysterical cases up to the time of the publication of his treatise in 1859. About the sixteenth century, Rislau, Diemerbroeck, and Th. Bonet sought to establish a relation between lesions of the genital organs met with in the bodies of hysterical women and the affection from which they suffered. About 1620, Ch. Lepois believed that he had established the existence of certain alterations of the brain in cases of hysteria. Hochstetter and Willis toward the beginning of the present century arrived at similar conclusions. That researches into the state of the genital organs have chiefly occupied those investigating hysteria is shown by the writings of Pujol, Broussais, Lovyer-Villermay, and, above all, by those of Piorry, Landouzy, Schutzenberger, and Duchesne-Duparc. Georget, Brachet, Girard, Gendrin, Bouillaud, Forget, and Lelut, about the fourth or fifth decades of the present century, made numerous autopsies on those dying when hysterical phenomena were in full activity, and concluded that the genital organs of these individuals revealed nothing in particular. This, in brief, is also the conclusion of Briquet. Jeanne d'Albret, the mother of Henry IV., who was all her life subject to hysterical headache, had her brain examined after death, but absolutely nothing was found. Vesalius made an autopsy with equally negative results on a woman who died from strangulation in an hysterical attack. Royer-Collard also found nothing in an old hysteric. Briquet believed—and I fully accord with this view—that in some of the cases of Ch. Lepois, Hochstetter, and Willis diseases such as chronic meningitis were present with the hysteria. He concludes that anatomy does not show anything positive as to the seat or nature of hysteria, except the suspicion of a certain degree of congestion in various parts of the brain.

While, however, hysteria may not have a morbid anatomy, it, like every other disease, has, in a correct sense, a pathology.

The ancients saw only the uterus when regarding hysteria. Hippocrates described the hysterical paroxysm and its accompanying disorders under the name of strangulation of the uterus. The ancients generally supposed that the disease originated in the ascent of the uterus to the diaphragm and throat. They believed that this accommodating organ could wander at will throughout the body, doing all manner of mischief. Hippocrates asserted that it was the origin of six hundred evils and innumerable calamities.

According to Sydenham,² the disorders which are termed "hysterical in women and hypochondriac in men arise from irregular motions of the animal spirits, whence they are hurried with violence and too copiously to a particular part, occasioning convulsions and pain when they exert

¹ *Op. cit.*

² *The Entire Works of Dr. Thomas Sydenham, newly made English from the Originals, etc.,* by John Swan, M. D., London, 1763, pp. 416, 417.

their force upon parts of delicate sensation, and destroying the functions of the respective organs which they enter into, and of those also whence they came; both being highly injured by this unequal distribution, which quite perverts the economy of nature." Speaking of the strangulation of the womb, or fits of the mother, he says: "In this case the spirits, being copiously collected in the lower belly and rushing with violence to the fauces, occasion convulsions in all the parts through which they pass, puffing up the belly like a ball."

After a time, the idea that the uterus was the exclusive seat of hysteria was in large measure supplanted by the view that the sexual organs in general were concerned in the production of hysterical phenomena. Romberg defined hysteria as a "reflex neurosis caused by genital irritation." Woodbury¹ concludes as late as 1876 that only where the pathological source of hysterical symptoms resides in the uterus or ovaries, cases may, with some show of propriety, be termed hysterical; and where the uterus and organs associated with it in function are not in a morbid condition no symptoms can be correctly called hysterical.

Bridges,² another American writer, in a paper on the pathology of hysteria, says that hysteria does not occur most frequently in women with diseased wombs, but in those whose sexual systems, by pampering and other processes, are abnormally developed and sensitive. He makes the same point with reference to the male sex. Sometimes, however, besides the emotional state in the male, there is actual disease of the sexual organs, caused by abuse or over-indulgence. Uterine disease and hysteria are sometimes like results of one cause, and not respectively cause and effect: women are hysterical oftener than men because the uterine function in woman's physiology plays a more important part in the production of emotional diseases than any organ of the male sex.

The truth would seem simply to be, that, as the uterus and ovaries are the most important female organs, they are therefore a frequent source of reflex irritation in hysterical patients.

Seguin³ adopts with some reservation Brown-Séquard's hypothesis that cerebral lesions produce the symptoms which point out their existence, not by destroying organs of the brain, but by setting up irritations which arrest (inhibit) the functions of other parts of the encephalon. He says that he finds no difficulty in believing that the same symptom may exist as well without as with a brain lesion. "In typical hysteria the functions of parts of the encephalon included in the right hemisphere, or in physiological relation with it, are inhibited by a peripheral irritation starting from a diseased or disordered sexual apparatus or other part; and in case of organic cerebral disease the same inhibitory action is produced. In both kinds of cases we may have loss of rational control over the emotions, loss of voluntary power over one-half of the body, and loss of sensibility in the same part."

Simply as a matter of passing interest, the attempt of Dupuy⁴ to frame a pathology of hysteria is worthy of attention. According to him, every

¹ *Medical and Surgical Reporter*, December 2, 1876.

local hysterical phenomenon is dependent upon an abnormal state of either lateral half of the upper part of the pons varolii. The centres of the pons, he holds, are perhaps merely passive in the process, only becoming organically implicated when various forms of permanent contractures and paralyses ensue.

The pathology of hysteria must be considered with reference to the explanation of the exact condition of the cerebro-spinal axis during the existence of certain special grave phenomena of hysteria, such as hemianæsthesia, hemiplegia, paraplegia, and contractures.

What is the probable state of the nerve-centres and tracts during these hysterical manifestations? If, for example, in a case of hysterical hemianæsthesia it is admitted that the brain of the other side of the body is somehow implicated, although temporarily, what is the probable condition of this half of the brain? Is the cerebral change vascular or is it dynamic? If vascular, is the state one of vaso-motor spasm or one of paresis, or are there alternating conditions of spasm and paresis? Are true congestions or anæmias present? If the condition is dynamic, what is its nature? Is it molecular? and if molecular in what does it consist? Is it possible to say absolutely what the pathological condition is in a disorder in which autopsies are obtained only by accident, and even when obtained the probabilities are that with fleeting life depart the changes that are sought to be determined?

Two hypotheses, the vaso-motor and the dynamic, chiefly hold sway. The vaso-motor, attractive because of its apparent simplicity, has been well set forth by Walton,¹ who contends that while it may not be competent to easily explain all hysterical symptoms, it will best explain some of the major manifestations of hysteria—for example, hemianæsthesia. Hemianæsthesia, he argues, may appear and disappear suddenly; it may be transferred from one side of the body to another in a few seconds; so blood-vessels can dilate as in a blush, or contract as in the pallor of fear, in an instant. In fainting the higher cerebral functions are suspended, presumably because of vaso-motor changes; therefore the sudden loss of function of one-half of the brain-centres, seen sometimes in hysterical hemiplegia and hemianæsthesia, may easily be imagined to be the result of an instantaneous and more or less complete contraction of cortical blood-vessels on that side. Neurotic patients have a peculiarly irritable vaso-motor nervous system. He records a case seen in consultation with H. W. Bradford. The patient had a right-sided hemianæsthesia, including the special senses, the sight in the left eye being almost wanting. The fundus of the right eye was normal; the left showed an extreme contractility of the retinal blood-vessels under ophthalmoscopic examination; these contracted to one-third their calibre, and the patient was unable to have the examination continued. The explanation offered is, that spasm of the blood-vessels on the surface of the left cerebral hemisphere had caused, by modification of the cortical cells, a right-sided hemianæsthesia, including the sight, and by reaching the meninges a left-sided spastic migraine, and by extending to the fundus of the left eye an intermittent retinal ischæmia.

The vaso-motor hypothesis is held by Rosenthal,² who, however, wrongly

¹ *Journal of Nervous and Mental Disease*, vol. xi., July, 1884, p. 424 *et seq.*

² "A Clinical Treatise on Diseases of the Nervous System," by M. Rosenthal, Vienna, translated by L. Putzel, M. D., vol. ii. *Wood's Library*, New York, 1879.

gives the spinal cord the preponderating part in the production of the symptoms. According to this author, the anæsthesia and analgesia present in hysteria conform to the law as established by Voigt with regard to the distribution of the cutaneous nerves. The sensory nerves form at the periphery a sort of mosaic corresponding to an analogous arrangement in the spinal cord. "It is evident," he says, "that the peripheral disorders in hysteria merely represent an exact reproduction of the central changes, and that the latter are situated, in great part, in the spinal cord." He attributes a large part of the symptoms of hysteria to a congenital or acquired want of resistance of the vaso-motor nervous system. "Motor hysterical disorders are also due in the beginning to a simple functional hyperæmia, but in certain forms the chronic hyperæmia may lead to an inflammatory process which may terminate (as in Charcot's case) in secondary changes in the columns of the cord and nerve-roots." When the brain is involved in hysteria, he holds that the most serious symptoms must be attributed to reflex spasms of the cerebral arteries and to the consequent cerebral anæmia.

The dynamic pathology of hysteria is probably believed in by most physicians, and yet it is difficult to explain. Thus, Briquet¹ says that hysteria manifests itself by derangement of the nervous action, and what is called nervous influence is something like electricity. It is simply the result of undulations analogous to those which produce heat and light; in other words, it is a mode of movement. Wilks² compares some of the conditions found in hysteria to a watch not going; it may be thought to be seriously damaged in its internal machinery, yet on looking into it there is found a perfect instrument that only needs winding up. As regards the brain being for a time functionless, the possibility of this is admitted by all, as in sleep or after concussion. He mentions the case of a young girl who had been assaulted, and had complete paralysis of motion and sensation. The shock had suspended for a time the operations of her brain, and organic life only remained. We have only to suppose that half of the brain is in this way affected to account for all the phenomena of hemianæsthesia.

According to the dynamic view, the central nervous system is at fault in some way which cannot be demonstrated to the eye or by any of our present instruments of research. The changes are supposed to be molecular or protoplasmic, rather than vaso-motor or vascular.

As innervation and circulation go hand in hand or closely follow each other, my own view is that both vaso-motor and molecular changes, temporary in character, probably occur in the central nervous system in grave hysterical cases.

Whatever the temporary conditions are, it is evident, on the one hand, that they are not states of simple anæmia or congestion, and, on the other hand, that they are not inflammations or atrophies. Patients with hysterical manifestations of the gravest kind as a rule are free for a time from their harassing and distressing symptoms. This could not be if these symptoms were due to lesions of an organic nature. Sudden recoveries also could not be accounted for if the changes were organic.

¹ *Op. cit.*

² *Lectures on Diseases of the Nervous System*, delivered at Guy's Hospital, by Samuel Wilks, M.D., F.R.S., Philada., 1883.

Lloyd¹ contends that most hysterical symptoms, if not all, are due to abnormal states of consciousness. The development of this idea constitutes his argument for the recognition of the disease as a true psychosis. In the reflex action, not only of the lower spinal cord and ganglia of special sensation, but of the highest centres of the brain, he sees the explanation of many of the characteristics of hysteria. In other words, he finds that the sphere of the disease is more especially in the automatic action of the brain and cord.

Dercum and Parker² have published the results of a series of experiments on the artificial induction of convulsive seizures which bear upon this discussion of the pathology of hysteria. The experiments were performed by subjecting one or a group of muscles to a constant and precise effort, the attention being at the same time concentrated on some train of thought. The position most frequently adopted was the following: The subject being seated, the tips of the fingers of one or both hands were placed upon the surface of the table, so as to give merely a faint sense of contact—*i. e.* the fingers were not allowed to rest upon the table, but were held by a constant muscular effort barely in contact with it.

Tremors commenced in the hands; these became magnified into rapid, irregular movements which passed from one limb or part to another until the subject was thrown into strong general convulsions. Opisthotonos, emprosthotonos, and the most bizarre contortions were produced in various degrees. No disturbances of sensation were at any time present. Disturbances of respiration and phonation were often present in a severe seizure, and the circulatory apparatus was profoundly affected. A flow of tears, and occasionally profuse perspiration, were sometimes induced. After severe seizures large quantities of pale urine were passed. The reflexes were distinctly exaggerated. No unconsciousness was ever observed, but a progressive abeyance or paresis of the will. Nitrite of amyl seemed to arrest the convulsive seizures at once.

In attempting to explain these phenomena Dercum and Parker refer to the induction of Spencer as to the universality of the rhythm of motion. Through the whole nervous system of every healthy animal a constant rhythmical interchange of motion takes place. What might be called nervous equilibration results. In man the will modifies and controls the action of the nervous system; it assists in maintaining nervous equilibrium when it is threatened. The will being withdrawn from the nervo-muscular apparatus, and this being subjected to strain, a disturbance takes place. This same explanation may be applied to some of the convulsive and other phenomena of hysteria.

Comparing and analyzing the various views, it may be concluded with reference to the pathology of hysteria as follows:

- (1) The anatomical changes in hysteria are temporary.
- (2) These changes may be at any level of the cerebro-spinal axis, but are most commonly and most extensively cerebral.
- (3) They are both dynamic and vascular: the dynamic are of some undemonstrable molecular character; the vascular are either spastic or parietic, most frequently the former.
- (4) The psychical element enters in that, either, on the one hand, violent mental stimuli which originate in the cerebral hemispheres are

¹ *Op. cit.* ² *Journal of Nervous and Mental Disease*, vol. xi., October, 1884, pp. 579-588.

transmitted to vaso-motor conductors,¹ or, on the other hand, psychical passivity or torpor permits the undue activity of the lower nervous levels.

ETIOLOGY.—Heredity has much to do with the development of hysteria. It is not that it is so frequently transmitted directly after its own kind, but this disorder in one generation generally indicates the existence of some ancestral nervous, mental, or diathetic affection.

Briquet² has shown that of hysterical women who have daughters, more than half transmit the disease to one or several of these, and, again, that rather more than half of the daughters of the latter also become hysterical. Amann, according to Jolly,³ has stated that in 208 cases of hysteria he proved with certainty an hereditary tendency 165 times—that is, in 76 per cent. This is too big to be true.

Briquet has also made some careful investigations into the subject of the health of infants born of hysterical mothers. The investigations were based upon a study of 240 hysterical women, with whom he compared 240 other patients affected with such diseases as fever, phthisis, cancer, diseases of the heart, liver, and kidneys, but without any hysterical symptoms. In brief, the result of his investigations was that children born of hysterical mothers die more frequently and at a younger age than those who are born of mothers not hysterical.

The relation of hysteria to certain morbid constitutional states has long been recognized, particularly its connection with the tubercular diathesis. This has been shown by numerous observers, especially among the French. The most valuable recent contribution is that of Grasset,⁴ who believes that a direct connection can be traced between the tubercular diathesis and hysteria. When the relations of hysteria to the scrofulous and tubercular diathesis are spoken of by him, it is not meant that hysterical subjects have tubercles in the lungs, but that these diatheses are found in various generations, and that among some subjects of the hereditary series the constitutional states manifest themselves as hysteria. It is not the evidences of hysteria with pulmonary and other tuberculous conditions that he is considering, but that hysteria may be, and often is, a manifestation of the tubercular diathesis. Two cases may present themselves: in one the neurosis is the only manifestation of the diathesis; in the other, it is continued in the same subject along with the other diathetic manifestations. In demonstration of his thesis he concludes with a series of most interesting cases, which he arranges into two groups. In the first, hysteria is the only manifestation of the tubercular diathesis; in the second, are simultaneous pulmonary and hysterical manifestations. In the first group he has arrayed eight personal observations and seventeen derived from various authors; in the second he has two personal and seventeen compiled observations.

Personal experience and observation go far to confirm the views of Grasset, although I recognize fully the strength of the objection of Brachat and Dubois and others that, phthisis being such a common complaint, it might be demonstrated by statistics that it was related to

¹ Rosenthal.

² *Op. cit.*

³ *Ziemssen's Cyclopædia of the Practice of Medicine*, vol. xiv., American translation.

⁴ "The Relation of Hysteria with the Scrofulous and the Tubercular Diathesis," by J. Grasset, *Brain*, Jan., April, and July, 1884.

almost any disease. Not only hysteria, but other neuroses or psychoses, have a close connection with the tubercular diathesis.

Among the insane and idiotic and among epileptics phthisis is of frequent occurrence. At the Pennsylvania Training School for Feeble-minded Children the frequency of phthisis among the inmates of the institution is one of the most striking clinical facts. The insane of our asylums die of pulmonary troubles oftener almost than of any other disease. The fact that hysteria is met with in the robust and vigorous does not invalidate the position taken, for the robust and vigorous who are not hysterical are not infrequently found in the descendants of the tuberculous.

Laycock¹ believed that the gouty diathesis was particularly liable to give rise to the hysterical paroxysm or to irregular forms of hysteria. Gairdner, quoted by Handfield Jones,² supports this view.

Gout in England plays a greater part in the production of nervous and other disorders than in this country, but even here its instrumentality is too often overlooked. In Philadelphia are many families, some of them of English origin, in which gout has occurred, sometimes of the regular type, but oftener of anomalous forms. Among the most striking examples of hysteria that have fallen under my observation, some have been in these families. In a few of them remedies directed to the lithæmic or gouty conditions in connection with other measures have been efficient. More frequently they have failed, for while a relation may exist between the neurotic disorder and the diathesis, it is not the diathesis, but the neurotic disorder, which we are called upon to treat.

That a certain mental constitution predisposes to hysteria cannot be doubted. Ribot³ describes, chiefly from Huchard,⁴ the hysterical constitution. It is a state in which volition is nearly always lacking. The prominent trait is mobility. The hysterical pass with incredible rapidity from joy to sadness, from laughter to tears; they are changeable, freakish, or capricious; they have fits of sobbing or outbursts of laughter. Ch. Richét compares them to children, who oftentimes can be made to laugh heartily while their cheeks are still wet with tears. Sydenham says of them that inconstancy is their most common trait: their sensibilities are aroused by the most trivial cause, while profounder emotions scarcely touch them. They are in a condition of moral ataxy, lacking equilibrium between the higher and lower faculties.

As to sex, it is almost unnecessary to say that hysteria occurs with greater frequency among females than males; and yet it is all important to emphasize the fact that it is not exclusively a disease of the former sex. Some statistics on this subject have been collected. In Briquet's often-quoted 1000 cases of hysteria, 50 only occurred in men. I believe, however, that the proportion of hysterical men to hysterical women is greater than this. Instead of a ratio of 1 to 20, as these statistics would indicate, 1 to 15 would probably be nearer the truth. Statistics upon this subject are deceptive.

The occurrence of hysteria in the male was little discussed before the publication of Briquet's great work, but since that time it has received

¹ *A Treatise on the Nervous Diseases of Women*, by Thomas Laycock, M. D., London, 1840.

² *Studies on Functional Nervous Disorders*.

³ *Diseases of the Will*.

⁴ Axenfeld et Huchard, *Traité des Névroses*, 2d ed., 1883, pp. 958-971.

great attention from the medical profession. Charcot¹ in some recent lectures at Salpêtrière has called attention to this subject. From 1875 to 1885 he says that five doctoral theses have been written on hysteria in men. Batault has collected 218 and Klein 80 cases. The *Index Catalogue* contains 102 references to hysteria in the male.

Hysteria in men may take on almost any form that it shows in women. It may occur in the strong, although more likely to be seen among the weak and effeminate. Even strong, vigorous workmen are susceptible, at times, to hysteria. According to Charcot, the duration of the affection differs somewhat in the two sexes. In male patients it lasts a long time and the symptoms are troublesome; in females the contrary is usually although not always the case. The occurrence of hysteria in the male sex has probably been overlooked through the tendency to class symptoms which would be regarded as hysterical in women as hypochondriacal in men.

One of the most typical half-purposive hysterical attacks that has ever come under my observation was in a literary man of some prominence. Hysterical syncope, contracture, hysterical breathing, hysterical hydrophobia, coccygodynia, hemiparesis, hemianæsthesia, and blindness are some other forms of hysteria in the male of which there are clinical records the result of personal observation. A remarkable case of hysterical motor ataxy was seen in a boy who was for some time a patient at the Philadelphia Polyclinic. Wilks² records several interesting cases of hysteria in boys. One simulated laryngismus stridulus, with paroxysmal suffocative attacks and barking. Another was a case of hysterical maniacal excitement; another was an example of malleation, or constant movement as in hammering; still others were instances of extreme hyperæsthesia, of anorexia, and of nervous dyspnoea. The same author also dwells on the hysterical perversion of the moral sense found in boys as in girls. He gives some instances clipped from English newspapers—attempts to poison, murder or attempts to murder, confessions false and true. Many instances could be added from our own sensational American sheets.

No age is free from a liability to hysteria. Its occurrence, however, at certain periods of life with great frequency is well known. The following table has been arranged from tables given by Briquet and Jolly, and shows that it is of most frequent occurrence between the ages of fifteen and thirty:

| Age. | Landouzy. | Georget. | Beau. | Briquet. | Scanzoni. | Total. |
|-----------------|-----------|----------|-------|----------|-----------|--------|

¹ *Le Progrès médical*, 1885.

² *Op. cit.*

Hysteria in the United States assumes almost every form, probably because we have here represented almost every race and nationality, either pure or mixed. While it cannot be clearly shown that certain races are much more prone to hysteria than others, the type of this disease is doubtless much influenced by racial and climatic conditions. Certain phases of the disease prevail in certain sections more than in others. Mitchell's¹ experience is that the persistent hystero-epilepsies, and the multiple and severe contractures which Charcot and others describe, are rare in this country among all classes, and especially uncommon in the lowest classes, among which Charcot seems to have found his worst and most interesting cases. He says that while his own clinic furnishes numerous cases of neural maladies, and while he has examples of every type of the milder form of hysteria, it is extremely uncommon to encounter the more severe and lasting forms of this disease. When Mitchell's *Lectures* were first published I was inclined to regard hystero-epilepsy of the grave type as of rare occurrence, and so stated in answer to a communication from him. Recently, as the result of a longer experience, I have become persuaded that some irregular forms are met with somewhat frequently in various sections of our country. It remains true, however, that in the Middle and Northern sections of the United States the graver hysterias of the convulsive type are not nearly as frequently observed as in the southern countries of Europe.

Dr. Guiteras, formerly physician to the Philadelphia Hospital, and Lecturer on Physical Diagnosis in the University of Pennsylvania, now in the United States marine hospital service, has for several years been on duty, most of the time, in Florida, the West Indies, and the Gulf of Mexico. In answer to an inquiry made by me, he writes: "Hysteria prevails with extraordinary frequency amongst the Cubans. It presents itself in the shape of excito-motory and mental phenomena, almost to the exclusion of all other manifestations. The motory anomalies comprise the whole range from mild hysterics to the gravest hystero-epilepsy. The latter is incomparably more frequent in Key West than in Philadelphia. The confirmed hystero-epileptics are few, but it is the rule for well-marked cases of hysteria to present occasionally, often only once in the course of the disease, hystero-epileptic seizures which may be of frightful intensity. By mental disorders I do not mean only the acute attacks of excitement and delirium which attend upon or take the place of convulsive attacks, but I mean also to include the chronic form of hysterical insanity, which is generally some variety of melancholia. These are the peculiarities of hysteria as seen by myself in the Latin race in the tropics. My experience teaches me that the Saxon race in the tropics shows the same peculiarities to a less extent."

In the region referred to by Guiteras it will be remembered there is a mixed population composed largely of Spanish, French, and Portuguese. Climatic and other local influences may have something to do with the particular form which this disorder assumes in these tropical or semi-tropical districts, but race would seem to be the most important factor. In the section on Hystero-epilepsy I will speak of the irregular type of this disorder, which has fallen most frequently under my own observation.

Hysteria in the negro is of somewhat frequent occurrence, and is more

¹ *Op. cit.*

likely to be of the demonstrative or convulsive than of a paralytic or negative form. Hysterical convulsions, particularly of the purposive kind, and hysterical mania, are often met with in the colored population of our large city hospitals and asylums.

The influence which climate exerts, like that of race, is rather on the type of hysteria than upon the disease itself. Hysteria is found in every climate, but in warm countries the disorder seems more likely to be mobile and dramatic than when found in the more temperate or colder zones.

Season and meteorological conditions have some influence on the production of hysterical attacks. It is well known that hysteria, chorea, and other allied nervous disorders are more likely to appear in the spring than at other seasons. This fact has been shown by various observers.

Hysteria may occur in any rank of life. It is not, as has been held by some, a disease of the luxurious classes. The American physician who has seen much of this disorder—and that means every physician of large practice—has met with hysterical cases in every walk of life. While this is true, however, hysteria of certain types is met with more frequently in certain social positions. Some of the remarks about race and climate apply also here. It is the type of the disorder, and its relative frequency among various classes, which are affected by social position. Young women of the richer classes, who have been coddled and pampered, whose wants and whose whims have been served without stint or opposition, often pass into hysterical conditions which do not have any special determining causative factor, or at least only such as are comparatively trivial. Occasionally, in them hystero-epilepsy, catalepsy, and the train of grave hysterical phenomena are observed. We are more likely, however, to have the minor and indefinite hysterical symptoms; or, if grave manifestations be present, they are most usually ataxia, paralysis, contractures, or aphonia, and not convulsive phenomena. Hysteria in our American cities is especially prevalent among certain classes of working-people, as among the operatives in manufacturing establishments. Dividing American society into the three classes of rich, middle, and poor, hysteria is most prevalent in the first and the last. It is, however, by no means absent in the middle class.

The absence of occupation on the one hand, and, on the other, the necessity of following work for which the individual is unfitted, particularly irritating lines of work, predispose to the occurrence of hysteria. It may be caused, therefore, either by no work, overwork, or irritating work. As to the special occupations, hysteria would seem to result most commonly in those positions where physical fatigue combines with undue mental irritation to harass and reduce the nervous system. In men it occurs often as the result of overwork conjoined with financial embarrassment. It is met with not infrequently among teachers, particularly those who are engaged in the straining and overstraining labor of preparing children for examinations. A good method of education is the best preventive; a bad method is one of the most fruitful causes of the affection. The injurious effect of American school or college life in the production of hysteria is undoubted, and should be thoroughly appreciated. Our educational processes act both as predisposing and exciting causes of this disorder. Both in our private and public educational institutions the

conditions are frequently such as to lead to the production of hysteria or to confirm and intensify the hysterical temperament. In our large cities all physicians in considerable practice are called upon to treat hysterical girls and boys, the former more frequently, but the latter oftener than is commonly supposed. Hysteria in boys, indeed, does not always meet with recognition, from the fact that it is in boys. Cases of hysteria in girls under twelve years of age have come under my observation somewhat frequently. About or just succeeding examination-time these cases are largely multiplied. The hysteria under such circumstances may assume almost any phase; usually, however, we have not to deal in such patients with convulsive types of the disease.

Clarke¹ has considered some of these questions in connection particularly with the physiological processes of menstruation, and its bearing upon the inability of girls to maintain equally with boys the stress of such competition.

The cramming processes which are resorted to in order to force children at fixed times from the lower to the higher grades of public schools, and more especially from grammar to normal or high schools, is a fruitful source of evil in this direction. It is not always so much hard study as it is the badly-arranged and too numerous subjects of study that make the strain. I have spoken of this in another connection as follows:² "Our children are too largely in the hands of those educationalists to whom Clouston refers,³ who go on the theory that there is an unlimited capacity in every individual brain for education to any extent and in any direction. Children varying in age and original capacity, in previous preparation, and in home-surroundings are forced into the same moulds and grooves. The slow must keep pace with the fleet, the frail with the sturdy, the children of toil and deprivation with the sons and daughters of wealth and luxury. A child is always liable to suffer from mental overwork when the effort is made to force its education beyond its receptive powers. Education is not individualized enough. The mind of the child is often confused by a multitude of ill-assorted studies. Recreation is neglected and unhealthy emulation is too much cultivated. In many communities admissions to various grades of public schools are regulated entirely by the averages obtained at examinations, instead of on the general record of the pupils in connection with proper but not too severe examinations. In consequence often, after the campaign of overwork and confusion called an examination, we see children developing serious disturbances of health or even organic disease—paroxysmal fever, loss of appetite, headache or neckache, disturbed sleep, temporary albuminuria, chorea, hysteria, and hystero-epilepsy."

The term students' hysteria has been applied to the neuromimetic disorders from which medical students frequently suffer during their attendance upon lectures. Some years since, when engaged in examining students upon the lectures upon the practice of medicine delivered by Professor DaCosta, I saw many illustrations of this affection,

¹ *Sex in Education, etc.*, by Edward H. Clarke, M. D., Boston, 1873.

² "Toner Lecture on Mental Overwork and Premature Disease among Public and Professional Men," delivered March 19, 1884, Washington, Smithsonian Inst., January, 1885.

³ *Clinical Lectures on Mental Diseases.*

some of which were very amusing. In a paper on hysteria which received the prize at the Physical Society of Guy's Hospital, P. Horrocks¹ writes that during the fortnight following the death of the late Napoleon, Sir James Paget was consulted for stone in the bladder by no less than four gentlemen who had nothing the matter with them. "How many students," says Horrocks, "are there, of one year's standing or more, who have not imagined and really become convinced that they were suffering from some disease, generally a fatal disease?" In such cases we have a combination of true psychological influence with overwork and the unhygienic surroundings for which our medical colleges are notorious.

It has been my personal experience that comparatively few cases of hysteria occur among female medical students. Not long since a thesis was presented at graduation by a woman medical student² on the curative effects of professional training in neurasthenic and hysterical women. In this she shows that there are certain relations of mind over body which enable it to modify bodily conditions and ward off disease when other remedies appear almost powerless. She illustrates the therapeutic power of mental impressions and occupations by two cases in which a judicious and careful course of study acted to cure severe nervous and uterine troubles. One of these women, who had suffered with neuræsthenia and general debility, severe nervous headaches, and other symptoms, was able during her last year at college to attend fifteen lectures a week, besides clinics, prepare for examination on five subjects, and was seldom troubled with even headache. She afterward was employed in hospital work, and could walk five miles a day without discomfort. That women medical students know when and how to take care of themselves during the menstrual period, and that they can, if they see fit, cease work or lighten their labors at that time, would partly account for their escaping from nervous break-down.

That any form of irritation in a patient predisposed to hysteria may act as an exciting cause in this affection has led Laségue to apply the term peripheral hysteria to certain cases. One of his cases was a girl fourteen years old, who, having suffered for a few hours with her eyes because of some sand thrown into one of them by a playmate, awoke the next morning with a spasm of the eyelid on that side, which rendered it impossible for her to open that eye; and it remained closed during four months. He considered that the irritation produced by the sand was not the immediate cause of the spasm, but that its long duration was an hysterical phenomenon. The patient afterward became the subject of hysterical manifestations. In another complete hysterical aphonia came on after a slight bronchitis. Another, after an attack of indigestion, refused to touch either food or drink for twenty-four hours, and later was troubled with regurgitation from constriction of the pharynx or œsophagus which lasted for some weeks.

Anæmia and chlorosis are frequent exciting causes of hysteria in children, particularly in girls.

Disorders of menstruation play a prominent part as exciting causes of

¹ *Med. and Surg. Reporter*, vol. xxxvii., Nov. 24, 1877.

² "The Therapeutic Value of Mental Occupation," by Hannah M. Thompson, M. D., *Medical and Surgical Reporter*, November, 1883.

special hysterical manifestations. The period of the establishment of the menstrual function is one that is particularly fertile in the production of hysteria, much more so than acquired disorders of menstruation occurring later. Menorrhagia, dysmenorrhœa, and certain local utero-vaginal disorders may act upon those predisposed to hysteria as exciting causes. These conditions themselves are, on the other hand, sometimes caused by nervous, hysterical states in the individual.

With reference to the very common assertions that continence on the one hand, and sexual over-indulgence on the other, are the most prolific causes of hysteria, the true stand to take is that neither of these positions is philosophically correct; for, as Briquet has shown, nuns on the one hand and prostitutes on the other are frequent victims of this protean disorder.

As affirmed by Jolly, sexual over-irritation, particularly that induced by onanism, more frequently causes hysteria than sexual abstinence or deprivation.

The occurrence of hysteria and hysterical choreas among pregnant women has long been recognized. Scanzoni, quoted by Jolly,¹ states that of 217 patients whom he had treated, 165, or 76 per cent. had been puerperal, and that of the latter not less than 65 per cent. had borne children more than three times. Cases of grave hysteria or hysterio-epilepsy have been aggravated by pregnancy and have led to premature labor.

Chrobak attacks the etiological problem of hysteria by referring its causation to movable kidneys! He observed 19 such patients in Vienna, 16 being in Oppolzer's clinic.² Three times no subjective symptoms accompanied the anomaly; eight times the trouble could be referred either to the dislocation of the kidneys or to disease of the same; and eight times the evidence of hysteria was unmistakable. Among the latter eight cases neither vaginal, uterine, nor ovarian conditions were recognized. He concludes that there is a direct nervous connection between the kidneys and the genital organs, and between both and hysteria.

In brief, the truth is that frequent or severe local irritation in any part of the body in an individual of the hysterical diathesis may act as the exciting cause of an hysterical paroxysm or of special hysterical manifestations. Irritation or disease of the uterus or ovaries may result in hysteria, as may the bite of a dog, a tumor of the brain, a polypus in the nose, a phymosis, an irritated clitoris, a gastric ulcer, a stenosis of the larynx, a foreign body in the eye, a toe-nail ulcer, or a movable kidney.

Whatever tends to exhaust the nervous system will also cause hysteria, but only in those who have some inherited predisposition to the disorder. C. Handfield Jones³ mentions heatstroke and severe physical labor as such causes. One of the sequelæ of heatstroke enumerated by Sir R. Martin, and quoted by Jones, is a distressing hysterical state of the nervous system, with an absence of self-control in laughing and crying, the paroxysm being followed by great prostration of nervous power.

³ *Op. cit.*

The effect of imitation in the production of hysteria has been known in all ages. Most of the epidemics and endemics of nervous disorders which have from time to time prevailed in various parts of the world have either been hysterical in character or have had in them a large element of hysteria. While it is impossible in a practical work to devote much space to this branch of the subject, a discussion of hysteria in its etiological relations would be imperfect without some reference to these outbreaks. In ancient times, in the Middle Ages, and within comparatively recent periods extraordinary epidemics have occurred. No country within the range of medical observation has been entirely free from them. Communities civilized and semi-civilized, Christian and Mohammedan, Protestant and Catholic, have had a fair share of the visitations. Some of them constitute epochs in history, and, as Hecker,¹ their greatest historian, has remarked, their study affords a deep insight into the work of the human mind in certain states of society. "They are," he says, "a portion of history, and will never return in the way in which they are recorded; but they expose a vulnerable part of man—the instinct of imitation—and are therefore very nearly connected with human life in the aggregate."

Some authors under hysteria, others under catalepsy, others under ecstasy, still others under chorea, have discussed these epidemics—a fact which serves to emphasize the truth that while these affections have points of difference, they have also an easily-traced bond of union. They are but variations of the same discordant tune. Briquet in an admirable manner sketches their history from the age of Pausanias and Plutarch to the time of Mesmer. Of American writers, James J. Levick² of Philadelphia has furnished one of the most valuable contributions to this subject.

In the year 1237 a hundred children or more were suddenly seized with the dancing mania at Erfurt; another outbreak occurred at Utrecht in 1278.

As early as the year 1374 large assemblages of men and women were seen at Aix-la-Chapelle affected with a "dancing mania." They formed circles and danced for hours in wild delirium. Attacks of insensibility, of convulsions, and of ecstasy occurred. The disease spread from Germany to the Netherlands. In a few months it broke out in Cologne, and about the same time at Metz. "Peasants," we are told, "left their ploughs, mechanics their workshops, housewives their domestic duties, to join the wild revelry, and this rich commercial city became the scene of the most ruinous disorder."

The festival of St. John the Baptist was one celebrated in strange wild ways in these early days. Fanatical rites, often cruel and senseless, were performed on these occasions. Hecker supposes that the wild revels of St. John's Day in 1374 may have had something to do with the outbreak of the frightful dancing mania soon after this celebration. It at least brought to a crisis a malady which had been long impending.

¹ *The Epidemics of the Middle Ages*, from the German of J. F. C. Hecker, M. D., Professor at the Frederick William University at Berlin, etc., translated by B. G. Babington, M. D., F. R. S., etc.; 3d ed., London, 1859.

² "An Historical Sketch of the Dance of St. Vitus, with Notices of some Kindred Disorders," *Med. and Surg. Reporter*, vol. vii., Dec. 21 and 28, 1861, p. 276, and Jan. 4 and 11, 1862, p. 322.

The Flagellants afford another illustration of an early religio-nervous craze. Self-flagellation was indulged in for generations before the fourteenth century, but it then became epidemic. A brotherhood of Flagellants was formed; they marched in processions carrying scourges, with which they violently lashed and scourged themselves. As late as 1843, Flagellant processions, but without the whips and scourging, were continued in Lisbon on Good Friday.

Strasburg was visited by the dancing plague in 1418. Those afflicted were conducted to the chapel of St. Vitus, where priests attempted to relieve them by religious ceremonies. The name St. Vitus's dance, still so common as a synonym for chorea, has come down to us because of the alleged wonderful doings of this saint in behalf of those affected during some of the dancing epidemics. Both Hecker and Madden¹ give interesting details of the personal history of St. Vitus, who was a Sicilian, born in the time of Diocletian, and even in childhood is said to have worked great miracles, and was delivered from many sufferings and torments. He died about the year 303. His body was moved to Apulia, afterward to St. Denys in France, and still later to the abbey of Corvey in Saxony. A legend was invented that St. Vitus, just before he bent his neck to the sword, prayed to God that he might protect from the dancing mania all those who should solemnize the day of his commemoration and fast upon its eve.

Another strange disorder called tarantismus derived its name from the fact that it was supposed to be caused by the bite of the tarantula, a ground-spider common in Apulia, Italy. According to Hecker, the word tarantula is the same as terrantola, a name given by the Italians to a poisonous lizard of extraordinary endowments. The fear of the insect was so general that its bite was much oftener imagined than actually received. The disorder was probably in existence long before the fifteenth century, although the first account of it, that of Nicholas Perotti, refers to its occurrence in this century. Many symptoms followed the bite or supposed bite: the individuals became melancholy, stupefied, lost their senses, and, above all, were irresistibly impelled to dance until exhausted and almost lifeless. It was believed that the results of the bite could be cured, or at least much benefited, by dancing to a certain kind of music. Tarantism was at its height in the seventeenth century. To this day, in some parts of Italy, dances called tarantellas are performed with intricate figures to marked time.

Abyssinia was visited by a dancing mania called the tigaretier, which, according to Hecker, resembled the original mania of the St. John dancers. It exhibited a similar ecstasy. Those affected with it were cured by dancing to the music of trumpeters, drummers, fifers, etc.

Levick says that the dancing mania of the fifteenth century is still kept in popular remembrance in some places by an annual festival, especially at Echtermarch, a small town in Luxembourg, where a jumping procession occurs annually on Whit Tuesday. In the year 1812, 12,678 dancers were in the procession.

The Anabaptists, a religious sect of the sixteenth century, exhibited many of the wild and grotesque phenomena of hysteria or hysterio-epilepsy.

¹ *Phantasmata; or, Illusions and Fanaticisms, etc.*, by R. R. Madden, F. R. S., London, 1857.

The French Calvinists or Camisards, who appeared near the close of the seventeenth century, were also the subjects of ecstasy and of peculiar fits of trembling. These trembleurs experienced convulsive shocks in the head, the shoulders, the legs, and the arms, and were sometimes thrown violently down.

About 1731 and later great crowds frequented the tomb of Deacon François de Paris, an advocate of the doctrines of Jansenius. It was reported that miracles were performed at his tomb: the sick were brought there, and often were seized with convulsions and pains, through which they were healed. The subjects of these attacks are sometimes spoken of as the Jansenist Convulsionnaires. The tomb was in the cemetery of St. Médard, and hence those who visited the place were also termed the Convulsionnaires of St. Médard. This disorder increased, multiplied, and disseminated, lasting with more or less intensity for fifty-nine years. Great immorality prevailed in the secret meetings of the believers.

Hecker gives some remarkable instances of the effect of sympathy or imitation exhibited on a smaller scale than in the epidemics of the Middle Ages. One is of a series of cases of fits in a Lancashire factory, the first one brought on by a girl putting a mouse into the bosom of another. In Charité Hospital in Berlin in 1801 a patient fell into strong convulsions, and immediately afterward six other patients were affected in the same way; by degrees eight more were attacked. At Redruth, England, a man cried out in a chapel, "What shall I do to be saved?" Others followed his example, and shortly after suffered most excruciating bodily pain. The occurrence soon became public; hundreds came, and many of them were affected in the same way. The affection spread from town to town. Four thousand people were said in a short time to be affected with this malady, which included convulsions.

Hecker in the edition of his work referred to has also a treatise on child pilgrimages.¹ These pilgrimages, like the dancing mania, occurred in the Middle Ages. The greatest was the boy crusade in the year 1212. The passion to repossess the Holy Land then had its grip on Catholic Europe. The first impulse to the child pilgrimages was given by a shepherd-boy, who had revelations and ecstatic seizures, and held himself to be an ambassador of the Lord. Soon thirty thousand souls came to partake of his revelations; new child-prophets and miracle-workers arose; the children of rich and poor flocked together from all quarters; parents were unable to restrain them, and some even began to urge them. A host of boys, armed and unarmed, assembled at Vendôme, and started for Jerusalem with a boy-prophet at their head. They got to Marseilles, and embarked on seven large ships. Two ships were wrecked, and not a soul was saved. The other five ships reached Bougia and Alexandria, and the young crusaders were all sold as slaves to the Saracens. In Germany child-prophets arose, especially in the Rhine countries and far eastward. An army of them gathered together, crossed the Alps, and reached Genoa. They were soon scattered; many perished; many were retained as servants in foreign lands; some reached Rome. A second child's pilgrimage occurred twenty-five years later. It was confined to the city of Erfurt. One thousand children wandered, dancing

¹ Translated by Robert H. Cooke, M. R. C. S.

and leaping, to Armstadt, and were brought back in carts. Another child's pilgrimage from Halle, in Suabia, to Mount St. Michel in Normandy, occurred in 1458.

In the convent of Yvertet in the territory of Liège, in 1550, the inmates were seized with a leaping and jumping malady. The disorder began with a single individual, and was soon propagated.

Sometimes the convulsive disorders of early days, especially those occurring in convents, were associated with the strange delusion that the subjects of them were changed into lower animals. Various names have been given to disorders of this kind, such as lycanthropia or wolf madness, zoomania or animal madness, etc. Burton in the *Anatomy of Melancholy* gives an interesting summary of these disorders, which are also discussed by Levick.

In 1760 a religious sect known as the Jumpers prevailed in Great Britain. They were affected with religious frenzy, and jumped continuously for hours. Other jumping epidemics have appeared at different times, both in Great Britain and in this country.

The New England witchcraft episode is of historical interest in connection with this subject of epidemic hysteria. This excitement occurred during the latter part of the seventeenth century. Adults and children were its subjects. The Rev. Cotton Mather records many cases, some of which illustrate almost every phase of hysteria. Individuals who were seized with attacks, which would now be regarded as hysterical or hystero-epileptic, were supposed to have become possessed through the machinations of others. Those who were supposed to be possessed were tried, condemned, and executed in great numbers. Many accused themselves of converse with the devil. The epidemic spread with such rapidity, and so many were executed, that finally the good sense of the people came to the rescue.

The nervous epidemics, nearly all religious, which have occurred in this country have usually been during the pioneer periods, and have therefore appeared at different eras as one part of the country after another has been developed. Kentucky, Tennessee, Virginia, and neighboring States were visited time and again. Even to-day we occasionally hear of outbreaks of this kind in remote or primitive localities, whether it be in the far South-west or in the woods of Maine.

David W. Yandell¹ has published a valuable paper on "Epidemic Convulsions," the larger part of the materials of which were collected by his father for a medical history of Kentucky. From this it would appear the convulsions were first noticed in the revivals from 1735 to 1742. Many instances are related of fainting, falling, trance, numbness, outcries, and spasms. The epidemic of Kentucky spread widely, reappeared for years, and involved a district from Ohio to the mountains of Tennessee, and even to the old settlements in the Carolinas. Wonderful displays took place at the camp-meetings. At one of these, where twenty thousand people were present, sobs, shrieks, and shouts were heard; sudden spasms seized upon scores and dashed them to the ground. Preachers went around in ecstasy, singing, shouting, and shaking hands. Sometimes a little boy or girl would be seen passionately exhorting the multitude, reminding one of the part taken by

¹ *Brain*, vol. iv., Oct., 1881, p. 339 *et seq.*

the children in the epidemics of the Middle Ages. A sense of pins and needles was complained of by many; others felt a numbness and lost all control of their muscles. Some subjects were cataleptic; others were overcome with general convulsions.

The term jerks was properly applied to one of the forms of convulsion. Sometimes the jerking affected a single limb or part. The Rev. Richard McNemar has given a graphic description of this jerking exercise in a *History of the Kentucky Revival*. The head would fly backward and forward or from side to side; the subject was dashed to the ground, or would bounce from place to place like a football, or hop around with head, limbs, and trunk twitching and jolting in every direction. Curiously, few were hurt. Interesting descriptions of the jerks can be found in various American autobiographical and historical religious works. In such books as the *Autobiography of Peter Cartwright*, a Western Methodist, for instance, striking accounts of some of the phases of these epidemics are to be found. Lorenzo Dow in his *Journal*, published in Philadelphia in 1815, has also recorded them.

Hysterical laughter was a grotesque manifestation often witnessed. The holy laugh began to be a part of religious worship. Dancing, barking, and otherwise acting like dogs, were still other manifestations. It is remarkable that, according to Yandell, no instance is recorded in which permanent insanity resulted from these terrible excitements.

The absurd and extraordinary exhibitions witnessed among the Shakers belong to the same category, and have been well described by Hammond and others.

In a *History of the Revival in Ireland in 1859*, by the Rev. William Gibson, instances of excitement that fairly rivalled those which occurred in our Western States are given. Cases of ecstasy are described.

The religious sect known as the Salvation Army, which has in very recent years excited so much attention, curiosity, and comment both in America and England, has much in common with the Jumpers, the Jerkers, and the Convulsionnaires. The frenzied excitement at their meetings, with their tambourine-playing, dancing, shouting, and improvising are simply the same phases of religio-hysterical disorder, modified by differences in the age and environment.

In 1878, in the district of Tolmezo, Italy, an epidemic of hysteria which recalls the epidemics of the Middle Ages occurred. It has been described by M. Léon Colin.¹ It was reported to the prefect of Undine that for three months some forty females living in the commune of Verzeguis had been attacked by religious mania. "From the report it appears that the first was in the person of a woman named Marguerite Vidusson, who had been the subject of simple hysteria for about eight years. In January, 1878, she began to suffer from convulsive attacks, accompanied by cries and lamentations. She was regarded as the subject of demoniacal possession, and on the first Sunday in May was publicly exorcised. Her affection, however, increased in severity; the attacks were more frequent and more intense, and were especially provoked by the sound of the church-bells and by the sight of priests. Seven months later three other hysterical girls became subject to convulsive and clamorous attacks. Here, again, an attempt was made to get rid of the sup-

¹ *Annales d'Hygiène*, quoted in *Lancet*, Oct. 16, 1880.

posed demon. A solemn mass was said in the presence of the sufferers, but was followed only by a fresh outbreak. At the time of the visit of the delegates eighteen were suffering, aged from sixteen to twenty-six years, except three, whose ages were respectively forty-five, fifty-five, and sixty-three years. Similar symptoms had also appeared in a young soldier on leave in the village." During the attacks the patients talked of the demon which possessed them, stated the date on which they were seized by it, and the names of the persons who were possessed before them. Some boasted of being prophetesses and clairvoyants and of having the gift of tongues. In all, the sound of church-bells caused attacks, and religious ceremonies appeared not only to aggravate the disease in the sufferers, but also to cause its extension to those not previously attacked. M. Colin points out that the soil is particularly favorable for the development of an epidemic of this nature. The people of Verzeguis are backward in education and most superstitious. Functional nervous diseases are common among them. The inhabitants of the village are largely cut off from intercourse with the adjacent country in consequence of comparative inaccessibility and the frequent interruption of communications by storms and floods. Craniometric observations on twelve of the inhabitants seemed to show that the brachycephalic form of skull predominated, and that the development of the cranium was slightly below the average. The epidemic proved extremely obstinate.

In Norway and New Caledonia similar hysterical outbreaks have been observed in recent times.

An endemic of hysteria from imitation occurred in Philadelphia in 1880. Some of the cases fell under my own observation. A brief account of them is given by Mitchell in his *Lectures*. The outbreak occurred in a Church Home for Children, to which Dr. S. S. Stryker was physician. The Home contained ninety-five girls and six boys; all of them were well nourished and in good condition. The epidemic began by a girl having slight convulsive twitchings of the extremities, with a little numbness. Attacks returned daily; respiration became loud and crowing. She soon had all the phenomena of convulsive hysteria. Many of her comrades began to imitate her bark. Soon another girl of ten was attacked with harsh, gasping breathing, with crowing, speechlessness, clutching at her throat, and the whole series of phenomena exhibited by the first girl attacked. Nine or ten others were affected in like manner, and many of the remaining children had similar symptoms in a slight degree. At first convulsions occurred irregularly; after a while they appeared every evening; later, both morning and evening. The presence of visitors would excite them. Many interesting hysterical phases occurred among the children. One night some of them took to walking about on their hands and knees; others described visions. The girls often spoke of being surrounded by wild beasts, and one child would adopt the fiction which another related in her hearing. The cases were scattered about in different hospitals, and made good recoveries in from one to two months.

The Jumpers or Jumping Frenchmen of Maine and Northern New Hampshire were described by Beard in 1880.¹ They presented nervous phenomena in some phases allied to hysteria. In June, 1880, Beard

¹ *Journal of Nervous and Mental Diseases*, vol. vii., 1880, p. 487.

visited Moosehead Lake and experimented with some of them. Whatever order was given them was at once obeyed. One of the Jumpers, who was sitting in a chair with a knife in his hand, was told to throw it, and he threw it quickly so that it struck in a beam opposite; at the same time he repeated the order to throw it with a cry of alarm. They were tried with Latin and Greek quotations, and repeated or echoed the sound as it came to them. They could not help repeating any word or sound that came from the person that ordered them. Any sudden or unexpected noise, as the report of a gun, the slamming of a door, etc., would cause them to exhibit some phenomena. It was dangerous to startle them where they could injure themselves, or if they had an axe, knife, or other weapon in their hands. Since the time of Beard's observation accounts of their doings have now and then found their way into newspapers. One recent account tells of one of these peculiar people jumping from a raft into the Penobscot River on an order to jump.

Hammond¹ has described under the name *Miryachit* an affection which seems to be essentially the same disorder as that of which the Jumpers are the victims. He quotes from a report of a journey from the Pacific Ocean through Asia to Europe by Lieutenant B. H. Buckingham and Ensigns Geo. C. Foulk and Walter McLean of the United States Navy, an account of this disease. The party made their first observations on this affection while on the Ussuri River in Siberia. The captain of the general staff approached the steward of the boat suddenly, and without any apparent reason or remark clapped his hand before his face; instantly the steward clapped his hand in the same manner, put on an angry look, and passed on. When the captain slapped the paddle-box suddenly, the steward instantly gave it a similar thump. Some of the passengers imitated pigs grunting or called out absurd names, etc.; the poor steward would be compelled to echo them all. The United States naval officers were informed that the affection was not uncommon in Siberia, and that it was commonest about Yakutsk, where the winter cold is extreme. Both sexes were subject to it, but men much less than women. It was known to Russians by the name of *Miryachit*.

In both these classes of cases a suggestion of some kind was required, and then the act took place independently of the will. "There is another analogous condition known by the Germans as *Schlafrunkenheit*, and to English and American neurologists as *somnolentia* or *sleep-drunkenness*. In this state an individual on being suddenly awakened commits some incongruous act of violence, oftentimes a murder. Sometimes this appears to be a dream, but in others no such cause could be discovered." Curious instances are mentioned by Hammond of this disorder.

The phenomena of automatism at command in hypnotized subjects have much similarity to the phenomena of these affections, and the same explanation to a certain extent will answer for both.

Paget² has ably discussed the subject of *neuromimesis* in general, and Mitchell³ devotes two lectures to its consideration. As already stated when discussing the synonyms of hysteria, the mistake must not be made of supposing all cases of hysteria to be instances of *neuromimesis*; but, as Mitchell remarks, the hysterical state, however produced, is a fruitful

¹ *New York Med. Journ.*, Feb. 16, 1884.

² *Op. cit.*

³ *Op. cit.*

source of mimicry of disease in its every form, from the mildest of pains up to the most complete and carefully-devised frauds. "Its sensitiveness and mobility, its timidity and emotionalness, its greed of attention, of sympathy, and of power in all shapes, supply both motive and help, so that while we must be careful not to see mimicry in every hysterical symptom, we must in people of this temperament be more than usually watchful for this form of trouble, and at least reasonably suspicious of every peculiar or unusual phenomenon."

SYMPTOMATOLOGY.—At the outset of the discussion of the symptomatology of hysteria, hysterical cases should be divided into four classes—viz. (1) Cases in which the symptoms are involuntary; (2) cases in which the symptoms are artificially induced and become involuntary; (3) cases in which the symptoms are acted or simulated, but in which the patient, because of impaired mental power, is irresistibly impelled to their performance; (4) cases in which the symptoms are purely acts of deception which are under the control of the patient.

Keeping in mind these different classes, we will always be able to link to the phenomena of hysteria the psychical element which is present in all genuine cases of this disorder. To comprehend the existence of the psychical element in the first class, in which the manifestations are absolutely involuntary, may offer difficulties. In these cases, at a period more or less recent or remote, psychical stimuli may have acted to produce the hysterical phenomena, and, once produced, these have been repeated and intensified by habit, and continue independently both of volition and consciousness. The experiments of Dercum and Parker show how hysterical symptoms may be artificially induced and may get beyond the patient's control. The difference between induced and simulated manifestations must always be clearly borne in mind. To induce a set of phenomena a certain mechanism must be set in action, and this, through rational, explicable processes, leads to certain results. The psychical element enters here both positively and negatively—positively, in the determination to produce a certain train of events; negatively, in the condition of mental concentration or abstraction which is a part of the procedure. In the third class of cases acting or simulation is dependent upon the irresistible inclinations of the patient. This may seem to some an uncertain and even dangerous ground to take. I am convinced, however, after observing many hysterical cases, that acts clearly purposive, so far as the particular performance is concerned, are sometimes the result of a general unstable mental condition. Some at least of these patients are as irresistibly impelled to swallow blood and vomit, to scream and gesticulate, etc., as is the monomaniac to commit arson, to ravish, or to kill. In the fourth class, the cases of pure, unmitigated, uncontrollable deception, the psychical element is very evident, although some may question whether such cases should be ranged under the banner of hysteria, where it is both convenient and customary to place them.

The symptoms of hysteria may develop in any order or after any fashion. The graver hysterical phenomena, such as convulsions, paralysis, and anæsthesia, often seem to come on suddenly, but usually this suddenness of onset is apparent rather than real. Minor hysterical symptoms, such as general nervous irritability, pains, aches, and discomforts, and mental peculiarities, have usually been present for a long

time. These minor evidences of the hysterical constitution are sometimes the only phenomena ever presented.

Todd¹ has described an expression of countenance which he designates as the *facies hysterica*. The characteristics of this expression are a remarkable depth and prominent fulness, with more or less thickness, of the upper lip, and a peculiar drooping of the upper eyelids. It would be absurd to assert that all hysterical patients presented this cast of countenance, but an appearance which approaches closely to this description is presented in a fair percentage of cases. It has seemed to me that male hysterics were more likely to have this peculiar *facies* than hysterical females.

The psychical peculiarities or mental disorders of hysteria form a large and important part of its phenomena. We have to deal not only with peculiar and diverse psychical manifestations, but to one form of mental disorder it is clinically convenient and correct to apply the designation hysterical insanity.

In the mildest cases of ordinary hysteria conditions of mental irritability and mobility are sometimes the only striking features. "Patients," says Jolly,² "are timid, easily overcome by any unexpected occurrence, sentimental, and sensitive. Every trifle annoys and upsets them; and there is this peculiarity—that a more recent stimulus may often effect a diversion in an exactly opposite direction."

As bearing upon the question of the mental state in hysteria, the confessions obtained by Mitchell from several patients are of great interest. One patient, who had learned to notice and dwell upon any little symptom, vomited daily and aroused much sympathy. She took little or no food. Spasms came on, and she confessed that every new symptom caused new anxiety, and that somehow she rather liked it all. She gradually lost all her symptoms except vomiting, and overcame this by desperate efforts. Another patient confessed to having played a game upon her doctor for a long time by pretending she took no food. She would get out of bed at night, but remain there all day; she filled up a vessel with water to make others believe she passed large quantities of urine, etc. Another patient, a girl of nineteen, who came on a litter from a Western State, after a time regained her feet. In her confession she stated that what she lacked was courage. She believed that she would have overcome her difficulties if any one had told her that nothing was the matter. "In looking back over the year with the light of the present," she says, "I can only say that I believe that there was really nothing the matter with me; only it seemed to me as if there was, and because of these sensations I carried on a sort of starvation process physical and mental."

The older and some of the more recent classifications of insanity recognize hysterical insanity as a distinct form of mental disease. Morel and Skae, however, in their etiological classifications, and Hammond, Spitzka, Mann, and Clouston in their recently-published works, give it a "local habitation and a name." Krafft-Ebing not only recognizes hysterical insanity as a distinct form of mental disease, but, after the German fashion, subdivides it quite minutely, as follows: First, transitory forms: *a.* with fright; *b.* hysterio-epileptic deliria; *c.* ecstatic visionary forms;

¹ *Reynolds's System of Medicine*, vol. ii. p. 656.

² *Op. cit.*

d. moria-like conditions. Second, chronic forms : *a.* hystero-melancholia ; *b.* hystero-mania ; *c.* degenerative states with hysterical basis.

Spitzka¹ speaks of chronic hysterical insanity as an intensification of the hysterical character, to which "a silly mendacity is frequently added, and develops *pari passu* with advancing deterioration." At the State Hospital for the Insane at Norristown and at the department for the insane of the Philadelphia Hospital cases of chronic hysterical insanity have come under my observation. Hammond under hysterical mania includes several different and somewhat distinct mental disorders.

With regard to the occurrence of hysterical manifestations amongst patients suffering from some well-recognized non-hysterical forms of insanity, a tour through any large asylum will afford abundant evidence. Cases of tremor closely simulating cerebro-spinal sclerosis have been observed frequently among the insane. Paralysis, contracture, hysterical joints, hysterical neuralgias, convulsions, and cataleptoid phenomena are among other hysterical manifestations which have fallen under personal observation among the insane of various classes.

A remarkable case of hysterical motor paralysis was observed at the State Hospital for the Insane at Norristown. This patient was an intelligent single woman about thirty-five years of age, of good family, well educated ; she had been a teacher and writer, and became insane through family and business troubles. When only eight years of age she was paralyzed for two years and a half, and had had at times during her life, before becoming insane, attacks of partial or complete unconsciousness. Prior to coming under observation she had been an inmate of an English private asylum. She was sick on shipboard coming to this country, and on her arrival was in a state of delirium and insomnia, with attacks of loss of sight. Four months later she developed mania with suicidal inclinations. Just before the development of this maniacal condition her lower limbs became comparatively helpless, and soon after she entirely lost their use. I found her in this condition, and examination showed no change in knee-jerk, electrical reactions, nutrition, nor genito-urinary conditions, which led me to diagnosticate the absence of any organic spinal trouble. The case was pronounced one of hysterical paralysis, and it was prophesied that she would eventually completely recover, probably suddenly. For one year her paralysis remained, her mental condition varying very greatly during this time—sometimes in a lethargic state ; sometimes with variable delusions and delirium ; occasionally violent and destructive, again peaceable and pleasant ; sometimes requiring strong anodynes and hypnotics. Fourteen months after her paralytic condition began, one day she suddenly threw away her crutches and ran up and down the corridor of the hospital. From that time she walked without difficulty, although her mental condition did not entirely clear.

I wish to impress the fact that because hysterical manifestations occur in a case of insanity it should not necessarily be diagnosticated as one of hysterical insanity. Monomania, melancholia, mania, parietic dementia, epileptic insanity, and other forms of mental disorder may at times have an hysterical tinge or hysterical episodes.

¹ *Insanity, its Classification, Diagnosis, and Treatment*, by E. C. Spitzka, M. D., New York, 1883.

The whole question of hysterical insanity is one of great difficulty. The psychical element is probably at the root of all cases of hysteria, but this does not justify us, as I have already stated, in declaring that all cases of hysteria are insane. In practical professional life we must make practical distinctions. In the matter before us distinctions are necessary to be made for legal as well as medical purposes. It might be right and proper to place a case of hysterical insanity in a hospital or asylum under restraint, but no one would dare to claim that every case of hysteria should be so treated.

Hysterical insanity may be conveniently subdivided into an acute and chronic form.

Acute hysterical insanity or hysterical mania is a disorder usually, in part at least, purposive, and characterized by great emotional excitement, which shows itself in violent speech and movement, and often also in deception, simulation, and dramatic behavior. The phenomena indicated by this definition may constitute the entire case, or, in addition, the patient may have, at intervals or in alternation, various other phases of grave hysteria, such as hystero-epileptic seizures or attacks of catalepsy, trance, or ecstasy.

In chronic hysterical insanity we have a persisting abnormal mental condition, which may show itself in many ways, but chiefly as follows: (1) A form in which occur frequent repetitions, over a series of years, of the phenomena of acute hysterical insanity, such as hysterical mania, hystero-epilepsy, catalepsy, etc.; (2) a form in which sensational deceptions—sometimes undoubtedly self-deceptions—are practised.

In a case of chronic hysterical insanity you may have both of these forms commingling in varying degree, as in the following case: G—— is a seamstress, twenty-one years of age. Although young in years, she is an old hospital rounder: she has at various times been in almost all the hospitals of the city. She has been treated for such alleged serious affections as fractured ribs, hemorrhages from the lungs, stomach, and vagina, gastric ulcer, epilepsy, apoplexy, paralysis, anæsthesia of various localities, amenorrhœa, dysmenorrhœa, and fever with marvellous variations of temperature. She has become the bane and terror of every one connected with her treatment and care-taking. She has developed violent attacks of mania, with contortions and convulsions, on the streets and in churches. Sums of money have been collected for her at times by those who have become interested in her as bystanders at the time of an attack or have heard of her case from others. She has made several pseudo-attempts at suicide. Recently an empty chloroform-liniment bottle tumbled from her bed at a propitious moment, she at the same time complaining of pain and symptoms of poisoning. She has refused to partake of food, and has been discovered obtaining it surreptitiously. Her large and prolonged experience with doctors and hospitals has so posted her with reference to the symptomatology of certain nervous affections that she is able at will to get up a fair counterfeit of a large variety of grave nervous disorders.

One of her recent attacks of hysteria was preceded by a series of hysterical phenomena, such as vomiting, hemorrhage, aphonia, ovaralgia, headache, and simulation of fever. She began by crying and moaning, which was kept up for many hours. She fell out of bed, apparently

insensible. Replaced in bed, she passed into a state closely simulating true acute maniacal delirium. She shrieked, cried, shouted, and moaned, threw her arms and legs about violently, and contorted her entire body, snapping and striking at the nurses and physicians in attendance. At times she would call those about her by strange names, as if unconscious of the true nature of her surroundings. Attacks of this kind were kept up for a considerable period, and after an interval of rest were repeated again and again.

Many of the extraordinary facts which fill the columns of the sensational newspapers are the results of the vagaries of patients suffering from the second of the forms of chronic hysterical insanity. "When," says Wilks,¹ "you see a paragraph headed 'Extraordinary Occurrence,' and you read how every night loud rapping is heard in some part of the house, how the rooms are being constantly set on fire, or how all the sheets in the house are torn by rats, you may be quite sure that there is a young girl on the premises." It is unnecessary to add that said girl is of the hysterical genus.

A story comes from an inland town, for instance, of a respectable family consisting, besides the parents, of three daughters and six sons, one of whom died of pneumonia. Since his death the family had been startled by exciting and remarkable events in the house—a clatter of stones on the kitchen floor, the doors and windows being closed; shoes suddenly ascending to the ceiling and then falling to the floor, etc. Search revealed nothing to explain the affair. As throwing light upon this matter, a visitor, who confessed his inability to explain the occurrences, nevertheless referred to one of the daughters as looking like a medium.

Charcot and Bourneville give frequent instances of extraordinary self-deceptions or delusions among hysterical patients. The story of an English lady of rank, who reported that she was assaulted by ruffians who attacked her in her own grounds and attempted to stab her, the weapons being turned by her corsets, is probably an example of this tendency. Investigation made by the police force threw grave doubts upon the story.

Many of the manifestations classed as hysterical by medical writers are simply downright frauds. The nature of others is doubtful. The erratic secretion of urine, for example, has frequently engaged the attention of writers on nervous diseases, and has awakened much controversy. American hysterics are certainly fastidious about this matter, as I have not yet met, in a considerable experience, with a single example of paruria erratica. Charcot² refers sarcastically to an American physician who in 1828 gravely reported the case of a woman passing half a gallon of urinous fluid through the ear in twenty-four hours, at the same time spirting out a similar fluid by the navel. He also alludes to the case of Josephine Roulier, who about 1810 attained great notoriety in France, but was discovered by Boyer to be a fraud. This patient vomited matter containing urea, and shortly after came a flow of urine from the navel, the ears, the eyes, the nipples, and finally an evacuation of fecal matters from the mouth.

Hemorrhages from eyes, ears, nostrils, gums, stomach, bowels, etc.

¹ *Op. cit.*

² *Op. cit.*

have often been observed among the hysterical; these cases sometimes being fraudulent and sometimes genuine. In the Philadelphia Hospital in 1883 was a patient suffering from grave hysteria, vomiting of blood being a prominent symptom. Although close watch was kept, several days elapsed before it was discovered that she used a hair-pin to abrade the mucous membrane of her nose, swallowed the blood, which passed into the throat, and then vomited it.

Sir Thomas Watson tells of a young woman who made a hospital surgeon believe that she had stone in the bladder; and Fagge, of a patient who had been supposed to have hydatid in the liver, and who produced a piece of the stomach of a rabbit or some other small animal, which piece she declared she had vomited. A few hours later she again sent for her medical man to remove from her vagina another fragment of the same substance.

A case is reported by Lopez¹ of spiders discharged from the eye of an hysterical patient. He regarded the case as one of hysterical monomania. Fragments of a dismembered spider were undoubtedly from time to time removed from the eye of the patient. Lopez believed that at first the fragments may have got into the eye accidentally, but that afterward the patient, under the influence of a morbid condition, introduced them from day to day. The total number of spiders removed in fragments was between forty and fifty. Silvy² relates a case in which a large number of pins and needles made their exit from a patient. Other needle cases are given, and also examples of insects and larvæ discharged from the human body. In one case worms crawled out of the nose, ears, and other natural openings; in another worms were found in active motion under the conjunctiva; in a third a beetle was discharged from the bladder, and several beetles were vomited by a boy.

Jolly³ records in a foot-note a case published in 1858, by I. Ch. Leitz of Pesth, of a young girl from whose eyes fruit-pips sprang, from whose ears and navel feces escaped, and from whose anus and genitals fleshy shreds came away, while worms with black eyes were vomited. He further tells of a woman from whose genitals four-and-twenty living and dead frogs passed, some of these, indeed, with cords of attachment. The birth of the frogs was witnessed and believed in by several physicians!

Hardaway⁴ reports a curious case with simulated eruptions. The woman appeared to be in fear of syphilis contracted by washing the clothes of a diseased infant. She had blebs irregularly distributed upon the fingers and arm of the left side; these, the doctor concluded, had been caused by the application of vitriol. He reports another case in which a woman had an eruption on her left arm, and the sores, instead of getting better under treatment, got worse. On one visit he found needle-scratches on the old sore. Nitric acid, according to Hardaway, is a favorite substance for the production of such eruptions. The best diagnostic test is that the blister is linear, while in pemphigus it is circular, unlike that which would be produced by a running fluid. Hysterical women have irritated their breasts with cantharides. Niemeyer⁵ mentions a woman at Krutsenberg's clinic who irritated her arm in such a way that amputation became neces-

³ *Op. cit.*

⁵ *Textbook of Practical Medicine*.

sary, and after that she irritated the stump until a second amputation had to be performed.

Nymphomania is a form of mental disorder which sometimes occurs among the hysterical; or it would perhaps be more correct to say that nymphomania and grave hysterical affections are sometimes associated in the same case. It is a condition in which is present extreme abnormal excitement of the sexual passion—a genesic, organic feeling rather than an affection associated with the sentiment of love. Hammond treats of it under the head of acute mania, and considers cases of nymphomania as special varieties of this disease. Undoubtedly, this is the correct way of looking at the subject in many cases. In man the corresponding mental and nervous condition often leads to the commission of rape and murder. In woman the affection is most likely to show itself with certain collateral hysterical or hysteroidal conditions, as spasms, hystero-epilepsy, and catalepsy, or with screaming, crying, and other violent hysterical outbreaks. Sometimes there is a tendency to impulsive acts, but this does not usually go so far as to lead to actual violence.

Nymphomaniacs may be intelligent and educated, and if so they usually resist their abnormal passions better than the ignorant. A number of nymphomaniacs have been under treatment at the Philadelphia Hospital. One case was an epileptic and also hysterical girl. She had true epileptic seizures, and at other times had attacks of a hysteroidal character. She would make indecent proposals to almost any one, and would masturbate and expose herself openly. She also had occasional maniacal attacks. She died in the insane department of the hospital.

Nymphomania and what alienists call erotomania are sometimes not differentiated in practice and in books. They are, however, really different conditions. Erotomania and nymphomania may be associated in the same case, but it is more likely that erotomania will not be present in a case of nymphomania. Erotomania may exist as a special symptom or it may be one of the evidences of monomania. It is found in both men and women. Patients with this condition may have no sexual feeling whatever. The individual has some real or imaginary person to love. It is rather the emotion of love which is affected, not the sexual appetite. It is shown by watching or following the footsteps of the individual, by writing letters, and by seeking interviews. In the history of Guiteau an incident of this kind is mentioned by Beard.¹ He followed a lady in New York whom he supposed to be the daughter of a millionaire—followed her, watched her house and carriage, and wrote letters to her. Out West he showed the same sort of attentions to another lady. He went to the house, but was kicked out. Many of the great singers have been followed in this way.

Some time ago I examined a man condemned to be hanged and within twenty-four hours of his death. He was an erotomaniac, whatever else he may have been. In the shadow of the gallows he told of a lady in the town who had visited him and was in love with him, and how all the women in the neighborhood were in love with him. He had various pictures of females cut from circus-posters in his cell. Erotomania is not generally found associated with hysteria.

Convulsions or general spasms are among the most prominent of hys-

¹ *Journal of Nervous and Mental Disease*, vol. ix., No. 1, January, 1882.

terical manifestations. Under such names as hysterical fits, paroxysms, attacks, seizures, etc. they are described by all authors. Their presence has sometimes been regarded as necessary in order that the diagnosis of hysteria might be made; but this, as I have already indicated, is an erroneous view.

Under hysterical attacks various conditions besides general convulsions are discussed by writers on hysteria; for instance, syncope, epileptiform convulsions, catalepsy, ecstasy, somnambulism, coma, lethargy, and delirium. According to the plan adopted in the present volume, catalepsy, ecstasy, somnambulism, etc. will be considered in other articles, and therefore my remarks at this point will be limited to hysterical general convulsions.

These convulsions differ widely as to severity, duration, frequency, motor excitement, and states of volition and consciousness. Efforts have been made to classify them. Carter¹ describes three forms as primary, secondary, and tertiary. In the primary form the attack is involuntary and the product of violent emotion; in the secondary it is reproduced by the association of ideas; and in the tertiary it is deliberately shammed by the patient. Lloyd² divides them into voluntary and involuntary forms, and discusses the subject as follows: "The voluntary or purposive convulsions are such as emanate from the conscious mind itself. Here are the simulated or foolish fits into which women sometimes throw themselves for the purpose of exciting sympathy or making a scene. I am convinced that a large number of hysteric fits are of this class: these are the patients who are cured by the mention of a hot iron to the back or the exhibition of an emetic. The involuntary forms of convulsion are more important. They happen in more sensible persons, and some of them are probably akin to starts, gestures, and other forcible or violent expressions of passions or states of the mind. A person wrings the hands, beats the breast, stamps upon the floor in an agony of grief and apprehension, and if terror is added he trembles violently. It is no great stretch of the imagination to suppose that great fear, anger, or some kindred passion, acting upon the sensitive nervous organization of a delicate woman or child, should throw them into a convulsion. This, in fact, we know happens. Darwin³ believes that in certain excited states of the brain so much nerve-force is liberated that muscular action is almost inevitable. He instances the lashing of a cat's tail as she watches her prey and the vibrations of the serpent's tail when excited; also the case of an Australian native, who, being terrified, threw his arms wildly over his head for no apparent purpose. The excito-motor reflexes of the cord may possibly take on true convulsive activity if released from the control of the will, which, as already said, is apt to be weak or in abeyance to this disease. Increased temperature is stated by Rosenthal to be always present in the great fits of epilepsy and tetanus, but absent in those of hysteria."

This subdivision of hysterical convulsions into voluntary and involuntary, or purposive and non-purposive, is a good practical arrangement; but the four groups into which I have divided all hysterical symptoms—namely, the purely involuntary, the induced involuntary, the impelled,

¹ *On the Pathology and Treatment of Hysteria*, London, 1853.

² *Op. cit.*

³ *Expression of Emotion*, etc.

and the purely voluntary—include or cover these two classes, and allow of explanation of special cases of convulsion which cannot be regarded as either purely shammed or as entirely, and from the first, independent of the will.

Absolutely involuntary attacks with unconsciousness constitute what are commonly called hystero-epileptic seizures, and will be described under Hystero-epilepsy.

The voluntary, impelled, or induced hysterical fit may be ushered in in various ways—sometimes with and sometimes without warning, sometimes with wild laughter or with weeping and sobbing. The patient's body or some part of it is then usually thrown into violent commotion or convulsion; the head, trunk, and limbs are tossed in various directions. Frequently the arms are not in unison with each other or with the legs. Screaming, shouting, sobbing, and laughing may occur during the course of the convulsive movement; sometimes, however, the patient utters not a word, but has a gasping, noisy breathing. She may talk in a mumbling, incoherent manner even during the height of the attack. She is tragic in attitude or it may be pathetic. The face is contorted on the one hand, or it may be strangely placid on the other. Quivering, spasmodic movements of the eyelids are often seen; but the eyes are not fixed and turned upward with dilated pupils, as in epilepsy. The patient does not usually hurt herself in these purposive attacks. She may or may not appear to be unconscious. She does not bite her tongue, nor does she foam, as does the true epileptic, although she may spit and sputter in a way which looks somewhat like the foaming of epilepsy. She comes out of the fit often with evident signs of exhaustion and a tendency to sleep, but does not sink into the deep stupor of the post-paroxysmal epileptic state. The paroxysm may last a few or many minutes. Large quantities of colorless urine are usually passed when it is concluded.

Hysterical paralysis, so far as extent and distribution are concerned, may be of various forms, as (1) hysterical paralysis of the four extremities; (2) hysterical hemiplegia; (3) hysterical monoplegia; (4) hysterical alternating paralysis; (5) hysterical paraplegia; (6) hysterical paralysis of special organs or parts, as of the vocal cords, the œsophagus and pharynx, the diaphragm, the bowels, and the bladder. Russell Reynolds¹ has described certain cases closely allied to, if not identical with, some forms of hysterical paralysis under the head of paralysis dependent upon idea. These patients have a fixed belief that they are paralyzed. The only point of separation of such cases from hysterical paralysis is the absence of other hysterical manifestations. Perhaps it would be better to regard the condition either simply as hysterical paralysis or as a true psychosis—an aboulomania or paralysis of the will. Such cases often last for many years.

Among the 430 hysterical cases of Briquet, only 120 were attacked with paralysis. In 370 cases of Landouzy were 40 cases of paralysis.

Briquet reports 6 cases in which paralysis attacked the principal muscles of the body and of the four extremities; 46 cases of paralysis of the left side of the body, and 14 of the right; 5 of the upper limbs only; 7 of the left upper limb, and 2 of the right; 18 of the left lower limb,

¹ *Brit. Med. Journ.*, 1869, pp. 378, 483.

and 4 of the right; 2 of the feet and hands only; 6 of the face; 3 of the larynx; and 2 of the diaphragm. Landouzy gathered from several authors the following results: General paralysis in 3 cases; hemiplegia in 14; 8 cases of paralysis of the left side; in other cases the side affected not indicated; and 9 cases of paraplegia.

Hysterical paralyses, no matter what the type, may come on in various ways—suddenly, gradually, from moral causes or emotional excitement, or from purely physical causes, as over-fatigue. They may have almost any duration, from hours or days to months or years, or even to a lifetime. They are frequently accompanied by convulsive or emotional seizures. They may be of any degree of severity, from the merest suspicion of paresis to the most profound loss of power. Hysterically paralyzed muscles retain their electro-contractility. Limbs which have become atrophied from disuse may show a temporary lessening of response, but this is quantitative and soon disappears. In rare cases, owing probably to the condition of the skin, the response to electricity is not obtained until the current has been applied for several minutes to the muscles.

Hysterical hemiplegia and monoplegia may simulate almost any type of organic paralysis. The paralysis is usually in a case of hemiplegia, confined to the arm and leg, the face being slightly, if at all, implicated. Hysterical paralysis, limited to the muscles supplied by the facial nerve, is very rare. According to Rosenthal, it sometimes coexists with paralysis of the limbs of the same side, and is usually accompanied by anesthesia of the skin and special senses. In a few rare cases, according to Mitchell, the neck is affected.

Several cases of hysterical double ptosis have come under my observation. The condition is usually one of paresis rather than paralysis. Cases of unilateral ptosis hysterical in character have also been reported. Alternating squints are sometimes hysterical, but they are usually of spasmodic rather than of paralytic origin.

Hysterical hemi-palsy is more frequent on the left than in the right side. In Mitchell's cases the proportion was four left to one right. The figures of Briquet have been given. It is usually, but not always, accompanied by diminished or abolished sensibility, both muscular and cutaneous. Electro-sensibility especially is markedly lessened in most cases.

When hemiplegia is of the alternating variety, the arm on one side and the leg on the other, or, what is rare in paralysis of organic causation, both upper extremities and one lower, or both lower and one upper, may be affected. Alternating hemiplegia of the organic type is usually a paralysis in which one side of the face and the leg and arm of the opposite side are involved.

Hysterical paraplegia is one of the most important forms of hysterical paralysis, and is sometimes the most difficult of diagnosis. It occurs usually, but not exclusively, in women. It comes on, particularly in young women, between puberty and the climacteric period, commonly between the twentieth and thirtieth years. Such a patient is found in bed almost helpless, possibly able to move from side to side, but even by the strongest efforts seemingly incapable of flexing or extending the leg or thigh or of performing any general movements of the foot. The feet are probably in the equino-varus position—extended and

turned inward. Certain negative features are present. The muscles do not waste to any appreciable extent, as they would in organic paralysis. Testing the knee-jerk, it is found retained, possibly even exaggerated. The electrical current causes the muscles to contract almost as well as under normal conditions; if a difference is present, it is quantitative and not qualitative in character. Paralysis of the bowels and bladder is not usually found, although it is but fair to state that this appears not to be the conclusion arrived at by some other observers.

Paralysis or paresis of the vocal cords, with resulting aphonia, is a common hysterical affection. Hysterical aphonia is also due to other conditions—for instance, to an ataxia or want of co-ordinating power in the muscles concerned in phonation; or to spasm, real or imaginary, in the same parts. Hysterical paralysis of the vocal cords is almost invariably bilateral; viewed with the laryngoscope, the cords are seen not to come together well, if at all. One may be more active than the other; but a distinct one-sided paralysis of this region nine times out of ten indicates that the case is not hysterical.

The following case is of interest, not only because of the aphonia, but because also of the loss of the power of whispering. The patient, a young lady of hysterical tendencies, while walking with a friend stumbled over a loose brick and fell. She got upon her feet, but a moment or two after either fainted or had a cataleptoid attack. Several hours later she lost her voice and the power of whispering. She said that she tried to talk, but could not form the words. This condition had continued for ten months in spite of treatment by various physicians. She carried a pencil and a tablet, by means of which she communicated with her friends. She had also suffered with pains in the head, spinal hyperæsthesia, and occasional attacks of spasm. Laryngoscopic examinations showed bilateral paresis of the vocal muscles, without atrophy. The tongue and lips could be moved normally. She was assured that she could be cured. Faradic applications with a laryngeal electrode were made daily; tonics were given; and the patient was instructed at once to try to pronounce the letters of the alphabet. In less than a week she was able to whisper letters, and in a few days later words. In three weeks voice and speech were restored. Just as this patient was recovering another came to be treated for loss of voice. She was markedly aphonic, but could whisper without difficulty. She was told, to encourage her, that she need not be worried about her loss of voice, as another patient, who had lost not only her voice, but the ability to whisper, had recovered. The patient returned next day unable to whisper a syllable. She made, however, a speedy recovery. Under the name *apsithyria*, or inability to whisper, several cases of this kind have been reported by Cohen.

Hysterical paralyses of the pharynx and of the œsophagus have been reported, but are certainly of extreme rarity. Hysterical dysphagia is much more frequently due to spasm or a sensation of constriction.

Paralysis of the diaphragm in hysteria has been described by Duchenne and Briquet. I have had one case under observation. The abdomen is drawn inward instead of being pushed outward in the act of inspiration in organic paralysis of the diaphragm; this condition is simulated, but not completely or very closely, in the hysterical cases. In some of the

cases of nervous breathing, which will be referred to hereafter, the symptoms are rather of a spastic than of a paretic affection of the diaphragm.

Paralysis or paretic states of the stomach and intestines are not uncommon among the hysterical, and produce tympanites, one of the oldest symptoms of hysteria. Jolly asserts that this "sometimes attains such a degree that the patients can be kept afloat in a bath by means of the balloon-like distension of their bellies"! The loss of power in the walls of the stomach and bowels is sometimes a primary and sometimes a secondary condition. The abdominal phantom tumors of hysterical women sometimes result from these paralytic conditions. These abdominal tumors are among the most curious of the phenomena of local hysteria. At one time two such cases were in the women's nervous wards of the Philadelphia Hospital. Both patients had been hysterical for years. In the first the tumor occupied the middle portion of the abdomen, the greater portion of its bulk more to the right of the median line. It was firm and nearly spherical, and the patient complained of pain when it was handled. She was etherized, and while under ether, and during the time that she was vomiting from the effects of the anæsthetic, the tumor disappeared, never to return. The other patient had a similar tumor for three days, which disappeared after the etherization of the first case.

Mitchell¹ has recorded some interesting paretic and other hysterical disorders of the rectum and defecation. Great weakness, or even faintness, after each stool he has found not uncommon, and other more formidable disorders occur. A patient who had been told that her womb was retroverted and pressing upon her rectum, interfering with the descent and passage of the feces, was troubled with hypersensitiveness of the lower bowel. This condition Mitchell designated as the excitable rectum. Patients in whom it is present apparently have diarrhœa; certainly they have many movements daily. Single stools, however, are small, and may be quite natural or they may seem constipated. The smallest accumulation of fecal matter in the rectum excites to defecation. One case had small scybalous passages every half hour. The forms of hysterical paresis or paralysis or pseudo-paralysis of the rectum observed by Mitchell were due—(1) to a sensory paralysis of the rectum; (2) to a loss of power in the rectal muscular walls; (3) a want of co-ordination in the various muscles used in defecation; (4) to a combination of two or of all of these factors. In rare cases the extrusive muscles act, but the anal opening declines to respond.

Hysterical locomotor ataxia, or hysterical motor ataxia, is an affection less common than hysterical palsy, but by no means rare. Various and diverse affections of motion are classed as hysterical ataxia by different authors. Mitchell speaks of two forms independent of those associated with vertigo. The first, that described by Briquet and Laségue, seems to depend upon a loss of sensation in both skin and muscles; the second often coexists with paralysis or paresis, and is an affection in which the patient has or may have full feeling, and is able to use the limbs more or less freely while lying down. As soon as she leaves the recumbent position the ataxia is very evident. She falls first to one side and then to the other. She "seems to be unable to judge of the extent to which balance is lost, and also to determine or evolve the amount of

¹ *Op. cit.*

power needed to overcome the effect." Mitchell believes that this disorder is common in grave hysteria, and is likely to be confounded with one of the forms of hysterical alternating spasm, in which first the flexors and then the extensors contract, the antagonistic muscles not acting in unison, and very disorderly and eccentric movements being the result. I have reported a case of hystero-epilepsy¹ in which a spasmodic condition closely simulated hysterical ataxia. The patient had various grave hysterical symptoms, with epileptoid attacks. She became unable to walk, or could only walk a few steps with the greatest difficulty, although she could stand still quite well. On attempting to step either forward or backward, her head, hips, shoulders, and trunk would jerk spasmodically, and she would appear to give way at the knees. No true paralysis or ataxia seemed to be present, but locomotion was impossible, apparently because of irregular clonic spasms affecting various parts of her body.

Mary Putnam Jacobi² has reported a case occurring in an Irish woman aged thirty-five years as one of hysterical locomotor ataxia. It is questionable whether this case was not rather one of posterior spinal sclerosis with associated hysterical symptoms. The existence of pain resembling fulgurating pains, and especially the absence of the patellar tendon reflex, would incline me to hesitate a long time before accepting the diagnosis of hysteria, particularly as it is known that organic locomotor ataxia often has a much-prolonged first stage, and that wonderful temporary improvements sometimes take place.

Ataxic symptoms of a mild form are of frequent occurrence in hysteria. They are shown by slight impairments of gait and difficulty in performing with ease and precision many simple acts, as in dressing, writing, eating, etc.

Hughes Bennett and Müller of Gratz call attention to the fact that young women may exhibit all the signs of primary spastic paralysis, simulating sclerosis, and yet recover.³ I have seen several of these cases of hysterical spasmodic paralysis, and have found the difficulties in diagnosis very great. These patients walk with a stiff spastic or pseudo-spastic gait, and as, whether hysterical or not, the knee-jerk is likely to be pronounced, their puzzling character can be appreciated.

In one class of cases, which cannot well be placed anywhere except under hysteria, a sense or feeling of spasm exists, although none of the objective evidences of spasmodic tabes can be detected. Comparing these cases to those which Russell Reynolds describes as paralysis dependent upon idea, they might be regarded as cases of spasm dependent upon idea.

One case of this kind which was diagnosticated as lateral sclerosis by several physicians recovered after a varying treatment continued for several years, the remedy which did him the most good being the actual cautery applied superficially along the spine. The patient described his condition as one of "spasmodic paralysis of all the muscles of the body." If sitting down, he could not at once get up and walk or run, but would have to use a strong effort of his will, stretching his limbs several times

¹ *Journal of Nervous and Mental Disease*, vol. ix., No. 4, October, 1882.

² *Arch. of Medicine*, New York, 1883, ix. 88-93.

³ Quoted by Althaus: *On Sclerosis of the Spinal Cord*, by Julius Althaus, M. D., M. R. C. P., etc., New York, 1885, p. 330.

before getting on his feet. Movements once started could be continued without much difficulty. When his hands were closed he would be unable, at times, to open them except by a very strong effort of the will. If one was opened and the other shut, he could manipulate the latter with the former. He sometimes complained of a sensation as of a steam-engine pumping in his back and shaking his whole body. He would sometimes be in a condition of stupor or pseudo-stupor, when he had a feeling as if he was under the influence of some poison. The spasms or jumpings in the back he thought sometimes caused emissions without erections. He compared the feeling in his back to that of having a nerve stretched like a piece of india-rubber. The excitement of mind would then cause the nerve to contract and throb. This description shows that the symptoms were purely subjective. Examination of the muscles of the legs and arms did not reveal, as in true spastic paralysis, conditions of rigidity. The limbs would sometimes be stiff when first handled, volition unconsciously acting to keep them in fixed positions; but they would soon relax. The knee-jerk, although well retained, was not markedly exaggerated, as in spastic paralysis, nor was ankle clonus present. The patient did not get progressively worse, but his condition vacillated, and eventually he recovered. A friend of the patient, living in the same neighborhood and going to the same church, was affected with true lateral sclerosis. It is worth considering how far in an individual of nervous or hysterical temperament observation of an organic case could have influenced the production of certain subjective symptoms, simulating spasmodic tabes.

Certain special forms of chorea are particularly liable to occur in the course of cases of hysteria. The most common type of the chorea of childhood, if not strictly speaking hysterical, is frequently associated with a hysteroid state, and is best treated by the same measures that would be calculated to build up and restore an hysterical patient. The following conclusions, arrived at by Wood¹ after a clinical and physiological study of the subject of chorea, show that certain forms of chorea may be hysterical or imitated by hysteria:

1st. Choreic movements may be the result of organic brain disease.

2d. Choreic movements exactly simulating those of organic brain disease may occur without any appreciable disease of the nerve-centres.

3d. General choreic movements, as well as the bizarre forms of electric and rhythmical chorea, may occur without any organic disease of the nervous system.

To these propositions may be added a fourth—viz. Choreic movements may be the result of a peripheral irritation, or, in other words, may be reflex.

Hysterical rhythmical chorea is a form of chorea in which involuntary movements are systematized into a certain order, so as to produce in the parts of the body which are affected determinate movements which always repeat themselves with the same characters. The movements are strikingly analogous to the rhythmical movements, as those of salutation, which often occur in the second period of the hystero-epileptic attack. Rhythmical chorea should undoubtedly be arranged among the manifes-

¹ "Chorea: a Study in Clinical Pathology," by H. C. Wood, M. D., LL.D., *Therapeutic Gazette*, 3d Series, vol. i., No. 5, May 15, 1885.

tations of grave hysteria. An account of an interesting case of this kind is given in a lecture by Wood, reported by me in the *Philadelphia Medical Times* for Feb. 26, 1881.

As Charcot has shown, rhythmic chorea is usually of hysterical origin, although it may exist without any of the phenomena which usually characterize hysteria. In these cases the movements imitated are according to a certain plan; thus, they may be certain expressive movements, as some particular form of dancing or the so-called saltatory chorea. They may be, again, certain professional or trained actions, such as movements of hammering, of rowing, or of weaving. Charcot speaks of a young Polish girl in whom movements of hammering of the left arm lasted from one to two hours, and occurred many times in a day for seven years. He has also given an account of another case, a patient with various grave hysterical manifestations, who would have a pain and beating sensation in the epigastrium, accompanied by a feeling of numbness. The right upper extremity would then begin to move; this would soon be followed by the left, and then by the lower extremities; then would follow a succession of varied action, complex in character, but in which rhythm and time and correct imitation of certain intentional and rational movements could readily be recognized. The attacks could be artificially induced in this patient by pulling the right arm or by striking on the patellar tendons with a hammer. During the whole of the attack the patient was conscious. In another patient rhythmical agitations of the arm, the movement of wielding a hammer, were produced in the first stage; then followed tonic spasms and twisting of the head and arms, suggesting a partial epilepsy; finally, rhythmical movements of the head to the right and left took place, the patient at the same time chanting or wailing.¹

In the following case an hysterical jumping chorea was probably associated with some real organic condition or was due to malarial infection. The patient was a middle-aged man. During the war he received a slight shell wound in the back part of the right thigh, and from that time suffered more or less with numbness and some weakness of the right leg. He was of an active nervous temperament. About three months before coming under observation he had without warning a peculiar attack which, in his own words, came on as if shocks of electricity were passed through his head, back, limbs, and other parts of the body. In this attack, which lasted for fully an hour, he jumped two or three feet in the air repeatedly; his arms, legs, and even his head and eyes, shook violently. He was entirely conscious throughout, but said nothing except to ask for relief. His wife, who was present, stated that at first he was pale, and afterward, during the attack, he became almost turgid under the eyes. Attacks appeared to come at intervals of seven and fourteen days for a time, so that his family physician surmised that there might be some malarial trouble, and prescribed for him accordingly. They soon, however, became irregular in character, and did not occur at periodical intervals. After the attacks he would lie down and go to sleep; he did not, however, pass into the condition of stupor that is observed after a grave epileptic seizure. His sleep seemed to be simply that of an exhausted nervous system.

¹ Charcot's lectures in *Le Progrès médical* for 1885.

Hysterical tremor is of various forms and of frequent occurrence: a single limb, both upper or both lower extremities, or the entire body may be affected. In a case of hystero-epilepsy, which will be reported in the next article, the patient had a marked tremor of the left arm, forearm, and hand, which was constant, but worse before her attacks; it remained for many months, and then disappeared entirely. Caraffi¹ reports the case of an hysterical girl of eighteen, anæsthetic on the right side and subject to convulsive attacks, who fell on the right knee and developed an arthritis. At the Hôpital Beaujon service of Lefort and Blum she presented herself with the above symptoms, aphonia, and an uncontrollable tremor of the right lower extremity, and trophic disturbances of the same. Immobilization of the limb was tried without benefit, and Blum then stretched the sciatic, with complete relief of the tremor and of the troubles of sensibility and of nutrition.

Hysterical contracture, like hysterical paralysis, may assume a variety of forms: it may be hemiplegic, monoplegic, paraplegic, alternating, or local, as of the ocular muscles, the facial or neck muscles; laryngeal, pharyngeal, or œsophageal; of the fingers or of the toes.

Richardson² records the case of a young lady who saw in India a religious devotee with his leg flexed upon his body and fastened there. In a few hours she was found with her leg in a similar position, and this contracture remained until after she had been taken to London; then it disappeared as suddenly as it came. Conscious purpose could not have maintained the leg in such a position for an hour.

Some of the most remarkable cases of hysterical contracture are those chiefly studied by the French, which originate before or after convulsive seizures. Among the hystero-epileptics at Salpêtrière, Richer³ reports many varieties of contracture: one with hemianæsthesia and varying pain in the right side had permanent contracture with tremulousness of the lower extremities; another, with hemianæsthesia, pain, and frequent attacks of demoniacal delirium and paresis, had momentary contractures of the upper and lower extremities on the right side. In two other cases the contractures were of the hemiplegic form, while three others were paraplegic. In still other cases the contracture was monoplegic. Besides hemiplegic, monoplegic, and paraplegic contractures, I have seen illustrations of a number of local forms—among others, several remarkable cases of hysterical contractures of the wrist and hand and of the feet and toes, and one of hysterical torticollis. Hysterical contracture in any of its forms may occur as an isolated symptom or series of symptoms unconnected with the grave hysterical attack.

Many forms of hysterical local spasms occur. Hysterical strabismus from spasm of the ocular muscles has been observed. Several cases have come under observation in which hysterical blepharospasm was present. In these cases, when the lids are forced open, the eyes disappeared in an extraordinary manner, usually being drawn downward and toward the internal canthus. Hysterical facial spasm occurs, and is usually clonic. One of the most remarkable hysterical local spasmodic affections which has come under personal observation was reported by me in a paper on chorea.⁴ In this case the right ear twitched and moved up and down.

¹ *L'Encéphale*, June, 1882.

³ *Op. cit.*

² *Diseases of Modern Life.*

⁴ *Philada. Med. Times*, March 27, 1875.

The movement of the ear was peculiar; it continued nearly all the time, even when the patient's attention was not directed toward the part. The act seemed to be partially under the control of the will, as by a strong effort the left ear could be moved very slowly in the same up-and-down direction. The nostrils and upper lip were affected with twitching, and slight choreic movements were present in the entire right side of the body. The patient's general condition improved under treatment, but when last seen the local affection persisted, although it was not so severe.

Spasm of the pharynx, larynx, and œsophagus have been separated by several authors. In hysterical laughter spasmodic contraction of the laryngeal muscles occurs. Spasm of the glottis occurs in rare cases, according to Rosenthal, from the reflex effect of hyperæsthesia of the laryngeal mucous membrane, from irritation of the recurrent laryngeal nerve. Death from asphyxia has occurred in consequence of this form of spasm of the glottis.

Hysterical dysphagia, which is usually spasmodic, is sometimes a dangerous, and always an annoying, affection. An unmarried lady, forty years old, with a neurotic family history, a maternal uncle and aunt having been insane, at intervals since puberty had had various hysterical manifestations. After a severe winter, during which she had suffered more or less with rheumatism, she became depressed with reference to her spiritual condition: she had, in fact, a form of mild religious melancholia. After this had lasted for weeks she began to experience difficulty in swallowing. She would rise from the table suddenly, alarmed and gasping, and exclaiming that she could not swallow and was choking. She got so bad that she could not take anything but liquid food, and not nearly enough of this. She believed that her throat was gradually closing, and of course suspected cancer. She was assured that if any local obstruction existed it could be removed with one application of a probang. Cancer was also confidently excluded, and she was given iron, valerian, and quinine, and in a few days an instrument was passed down her throat. She was told that she would have no more difficulty. Tonics and full feeding were continued, and in less than a week she swallowed without any difficulty.

Of the so-called hysterical asthma or hysterical breathing I have seen several examples. A curious form of hysterical breathing, at least partly spasmodic, recently came to the Philadelphia Polyclinic—a young man twenty-one years of age, who confessed that he had been guilty of excessive masturbation for five or six years. He had been a moderate drinker and was the victim of an old hip disease. According to his story, this abuse had never appeared to have impaired his health until about one month before applying for treatment, when he began to have attacks of peculiar breathing. He would have a series of rapid, forced expirations which lasted for a period of from one to two or three minutes. He would then stop for a moment; then again the shallow breathing with forced expirations would ensue. He said that he breathed in this way because he thought he was going to die, and did so to keep alive. When he stopped he felt cold. He thought his belly did not go outward as it should in the act of breathing. During the time that the symptoms had been present he had had several frightful attacks of excitement, in one of which he ran breathing in the manner described to a

drug-store from one to two blocks away, jumping, gesticulating, and calling for remedies. He had an anxious expression of the face, a look of excitement and worriment. His pulse was 110 and weak. Respirations during these attacks ranged from 38 to 50.

Coates,¹ speaking of hysterical or nervous breathing, gives the details of five cases. Four of these had been supposed to be suffering from phthisis; the fifth was apparently a case of hypertrophy of the heart. The breathing was quick and shallow. The patients could not be induced to draw long breaths until the expedient was adopted of having them count twenty without taking breath. During this the lungs expanded perfectly, air entering freely into every part. Coughing, and even blood-spitting of a venous character, were present. They might perhaps be classed as cases of hysterical or simulated phthisis.

Vaginismus, or spasm of the vagina, may with propriety be regarded as hysterical in some but not in all cases. Spasmodic contracture of the sphincters of the bladder and anus is also mentioned by Rosenthal. Goose-flesh, according to the same author, is a frequent phenomenon in the hysterical, and is due to spasmodic contraction of the muscular fibres contained within the skin.

The sensorial affections of hysteria can be classified according either to character or location. According to the character of the sensory disturbance a good practical arrangement is into cases of (1) Anæsthesia; (2) paræsthesia; (3) hyperæsthesia; (4) neuralgias and localized pains,—although one of these classes may sometimes be difficult to separate from another, or a doubt may arise as to whether or not a special symptom should be placed under one or another head. In hysterical anæsthesia sensation is decreased or abolished; in paræsthesia it is faulty or perverted; in hyperæsthesia it is increased over a more or less extensive surface; in neuralgia, pain is confined to certain nerve-trunks. The localized pains are neuralgic or mimetic, and are found in special localities, as in joints and in the breast.

Anæsthesia is one of the most frequent of hysterical phenomena, but is not, as stated by some authorities, present in all cases of genuine hysteria.

In 400 hysterical cases Briquet found 240 positive examples of anæsthesia. In this statement, however, he does not include cases of insensibility of the conjunctiva of the left eye or those cases in which anæsthesia lasted but a few hours after an attack. It is safe to say that anæsthesia of some sort is present in from 60 to 75 per cent. of all cases of well-marked hysteria. Analgesia, or insensibility to pain, is present frequently when loss or diminution of sensibility to touch, pressure, heat and cold, etc., is not observed.

Hysterical anæsthesia, may be of various forms, according to the parts of the body affected, as general anæsthesia; hemianæsthesia; anæsthesia of the lower half of the body; anæsthesia of one limb or one side of the face; anæsthesia of mucous membranes; anæsthesia of muscles, bones, and joints; anæsthesia of the viscera.

General anæsthesia is extremely rare. No example of it has ever fallen under my observation, but by Briquet and others a few cases have been reported.

¹ *British Medical Journal*, 1884, ii. 13.

Hemianæsthesia has in recent years received much attention from neurologists. In hystero-epilepsy it is the rule to find it present, but it is also observed in cases without spasms. In hemianæsthesia the loss of sensation exists in one lateral half of the body. Parts are insensible to various methods of stimulation—to impressions of touch, pain, temperature, and weight. Sometimes the mucous membranes of the side affected are involved. The sight, hearing, taste, and smell are commonly impaired if not lost.

Much attention has been paid to the study of hemianæsthesia by French physicians. Chareot¹ has an admirable historical summary and clinical description of the condition, leaving little for others to add. Piorry, Macario, Gendrin, Szokalsky, and Briquet are referred to by him. Briquet found it present in 93 cases out of 400. It is of much more frequent occurrence on the left side. According to Briquet, 70 cases were affected on the left side to 20 on the right.

Next to hemianæsthesia, anæsthesia of the lower half of the body is most common in hysterical cases. While hemianæsthesia often presents itself conjoined with hystero-epileptic symptoms, anæsthesia of the lower half of the body may be present as frequently without as with convulsive manifestations. Anæsthesia of one limb or of one side of the face is almost as rare as general anæsthesia, but does occur.

Anæsthesia of mucous membrane is an old observation. It may affect mucous membranes everywhere—of the nose, pharynx, larynx, vagina, urethra, the bladder, rectum, etc. Many of the peculiar and apparently inexplicable hysterical symptoms are due to the presence of this anæsthesia—such symptoms, for instance, as want of inclination to evacuate the bowels or the bladder, absence of sexual desire, absence of sensibility when applications are made to the throat, etc. Loss of sensibility in muscles, bones, joints, and viscera may be present, but is of course frequently overlooked from want of minute investigation. In hemianæsthesia the viscera of the anæsthetic side are sometimes hyperæsthetic. Thus the ovary, as has been especially shown by Charcot, may be very painful on pressure when the abdominal wall is perfectly insensible.

A striking characteristic of hysteroid sensory disorders of the anæsthetic variety is the suddenness with which they come and go. A complete transference of anæsthesia from one side of the body to another may occur in a few seconds, either without special interference or under the use of metals or electricity.

The term achromatopsia is due to Galezowski. Hysterical achromatopsia is a condition in which there is a failure to appreciate colors. In Daltonism, or true color-blindness, one color may be taken for another; in achromatopsia the notion of color may be completely lost. These colors are found by the patient to disappear in a regular order, and return in a reverse order as the patient recovers. Some remarkable cases of this kind have been reported as occurring among French hysterics. A few examples of the same affection have been reported in America. Sometimes the patient has lost perception of one or several colors. When only one color is lost, it is usually the violet; if two, the violet and green; then in regular succession follow the colors of the spectrum.

¹ *Op. cit.*

Hysterical blindness and achromatopsia have been well studied by Charcot and Richer and others of the French school. Special articles on hysterical or simulated affections of the eye have also been published by Schweigger,¹ Harlan,² and others.

In several cases of hystero-epilepsy under my care both amblyopia and achromatopsia were present. In one of these cases the patient was unable to read print of any size or to distinguish any colors, although she could tell that objects were being moved before the eyes. An ophthalmoscopic examination showed a normal fundus. Each eye was tested for near vision. It was found that she could read quite well with the right eye, and not at all with the left. While reading at about sixteen inches a convex glass of three inches focus was placed in front of the right eye, but she still continued to read fluently.

C. H. Thomas of Philadelphia has given me the particulars of a case of a woman about thirty-eight years old, both of whose eyes were, to all appearances, absolutely blind. The attack came on suddenly, the apparent cause seeming to be worry over a sick child. Ophthalmoscopic and other examinations of the eye showed nothing. She had no perception of light. She could look without winking at a blinding reflection of a whitewashed fence. In six weeks under a mere tentative treatment she got absolutely well. S. D. Risley of Philadelphia,³ in a discussion at the Philadelphia Neurological Society, held that the feeble innervation of the hysterical patient was liable to diminish the range of accommodation and power of convergence, rendering the comfortable use of the eye impossible; and also that the feeble or deranged circulation in the hysterical individual might set up a group of symptoms in the eye presenting many of the characteristics of serious disease; which, however, were not simulated, but were, in fact, a relative glaucoma. While there was no absolute increase of intraocular tension, the normal tension of the eyeball was sufficient to interrupt the entrance of the feeble blood-stream into the eyes, and thus was set up the same group of symptoms as were present in actual increase of tension—viz. inadequate blood-supply to the retina, contracted field of vision, impaired central perception, diminished range of accommodation, and inability to use the eyes, particularly at a near point.

Very few observations in cases of hysteria have been made with the ophthalmoscope, and probably little is to be learned in this way. In one of Charcot's patients, however, Galezowski saw an infiltration and capillary reddening of the disc with fusiform dilatations of the artery.

What might be termed hysterical dilatation of the pupil is sometimes observed. In the case reported by Harlan, to be hereafter detailed, the patient, a young girl who had a train of hysterical symptoms, began to complain of blindness or imperfect vision in the right eye, the pupil of which was found to be dilated. No proof could be obtained of the use of any mydriatic. The pupil remained dilated when exposed to a bright light. The dilatation came and went at intervals, and finally disappeared under

¹ "On Simulated Amaurosis," by C. Schweigger, Prof. at the University of Berlin, *New York Medical Journal*, Feb., 1866.

the applications of a wooden magnet. W. Chester Roy has acquainted me with the facts of the case of a man who could at will alternately contract and dilate his pupils. This case would seem to lend color to the idea that the hysterical girl may have had voluntary control of the pupillary movements. In her case, however, only one pupil was involved. F. X. Dercum has given me the particulars of a case of rhythmical dilatation of the irides in a case of confirmed masturbation with hysterical symptoms.

Hysterical deafness has been observed and studied. Walton,¹ at Charcot's suggestion, has published the results of the examination at La Salpêtrière of 13 patients affected with hemianæsthesia with reference to anæsthesia of hearing. He divides hemianæsthetic patients into three classes: (1) Those with complete anæsthesia of one side, the other side remaining normal; (2) those having incomplete anæsthesia on one side, the other remaining normal; (3) those with anæsthesia more or less complete on both sides. In the first class anæsthesia of hearing extended to the deep parts of the ear; the membrane of the drum could be touched without eliciting any acknowledgment of sensation and without the least reflex movement. He also showed that the anæsthesia extended to the middle ear by the fact that insufflation by Politzer's air-douche produced no sensation in the ear of the affected side. In this class neither the watch, voice, nor tuning-fork was heard. In the second class, with incomplete anæsthesia on one side, the lost sensibility corresponded, as a rule, with that of the body in general. A common form was analgesia with thermoanæsthesia and diminution of the tactile sensibility. In the third class completeness of the anæsthesia is rarely the same on both sides, a common form being complete hemianæsthesia on one side and analgesia on the other.

A noticeable feature in all the cases under consideration was the uniformity with which the deafness for conveyance by the bone exceeded that for sounds conveyed by the ear. Walton says: "This is probably due to the fact that the vibrations conveyed to the ear by the air are better adapted for the irritation of the peripheral auditory apparatus than those conveyed by the bone. When, then, the receptive power of the auditory centres is lessened, as is probably the case in hysterical patients, the hearing for sounds conveyed by the bones disappears before that for sounds conveyed by the ear. This enfeeblement of the auditive centres in hysteria is quite analogous to that in old age, in which, as is well known, the perception for sounds conveyed by the bone disappears before that for sounds conveyed by the air, the former being sometimes completely lost before the age of sixty." His principal conclusions are as follows: (1) The sensibility of the deep parts of the ear, including the tympanum and middle ear, disappears in hysterical hemianæsthesia with that of other parts of the body, and in the same degree. (2) The degree of deafness corresponds with that of the general anæsthesia, being complete when the latter is complete, and incomplete when the latter is incomplete. (3) When loss of hearing is incomplete, the deafness for sounds conveyed by the bone exceeds that for sounds conveyed by air. (4) When the transfer is made, the hearing, as well as the general sensibility of the deep parts of the ear, improves on one side (allowance being made for accidental

¹ *Brain*, January, 1883.

lesions in the ear itself) in exactly the same degree in which it disappears on the other.

The following case has been kindly furnished to me by Charles S. Turnbull, the patient having in the first instance come to Philadelphia to consult his father, Laurence Turnbull: The patient was a young lady from New Jersey, eighteen years old. Her general health was good, although at times she had a pale and anxious look. She had never had any unusual sickness. Soon after the death of her mother, for whom she grieved very much, she began to grow deaf, and was for a time treated by her family physician. When she first came to Philadelphia she was absolutely deaf, but the most careful examination failed to discover a cause for the deafness in any affection of the external or middle ear. A current from ten cells of a galvanic battery was painful, but elicited no sound. She declared that she could not hear a musical box held close to the side of her head. In communicating with her, everything had to be written. A faradic current was used daily to her ears. Suddenly one morning, after a powerful current had been applied, her hearing returned, but before she came back for treatment the next day it had again left. The electrical treatment was continued: each day the hearing stayed longer and longer, and finally returned in full force and remained good.

By hysterical paræsthesia is meant that form of perverted sensation which is not distinctly depressed on the one hand or markedly increased on the other. Under this head would come such conditions as numbness, formications, prickling and tingling sensation, the sensation of a ball in the throat or globus hystericus, etc. These forms of perverted sensation are quite common among the hysterical.

Hyperæsthesia may present itself in almost any locality, its areas of distribution corresponding very well to those which have been given for anæsthesia. Hyperæsthesia of the special senses is of especially frequent occurrence. Great sensitiveness to sounds and to bright lights or to particular colors is commonly observed. What might be termed hysterical tinnitus aurium is met with occasionally.

Perversions of the senses of smell and taste are among the rarer phenomena in the sensory sphere in hysteria. These may be of three kinds: the senses may be completely obtunded; they may be hyperacute; or they may show peculiar perversions. To some individuals of the hysterical temperament certain smells are almost unendurable, and these may be odors which to others are particularly pleasant. In like manner, certain articles of food or drink may be the source of great discomfort or absolute suffering. It is one of the oldest of observations that hysterical and morbid cravings for disagreeable or disgusting substances sometimes exist.

In one group of hysterics the presence of pain is the predominating feature. Some of the situations in which hysterical pains are most frequently felt are the head, the pericardial or left inframammary region, over the stomach and spleen, the left iliac region, the region of the kidneys, the sacrum, the hip, the spine, the larynx and pharynx, one or both mammae, or over the liver and the joints. Of these locations, omitting the consideration of headache, the most common seats of hysterical pain are the spine, the breasts and inframammary region, the left iliac or ovarian region, the sacrum or coccyx, and the joints.

Charles Fayette Taylor, in a brochure on sensation and pain,¹ has given a philosophical explanation of such pain, drawing largely from Carpenter, Bain, Spencer, and others. The pith of the matter is that many of our sensations are centrally initiated, the memory of previous objective sensations. "Pain is different from ordinary sensations, in that it requires an abnormal condition for its production, and that it cannot be produced without that abnormal condition. Hence it is impossible to remember pain, because the apparatus does not exist for causing such a sensation as pain after the fact or when it is to be remembered. Memory is a repetition, in the nerve-centre, of energy which was first caused by the sensory impulse from without. But centrally initiated sensations may be mistaken, in consciousness, for pains depending wholly on a certain intensity of excitability in the cerebral mass."

A large percentage of all cases of hysteria complain more or less of spinal irritation. Spinal periostitis, spinal caries, and perhaps some cases of spinal meningitis, are organic diseases which may give rise to tenderness on pressure along the spine; but the majority of cases of spinal irritation are found among neurasthenic or hysterical patients. So much has already been written about spinal irritation that much time need not be spent on the subject, were it not that even yet many practitioners are inclined to regard cases as organic spinal trouble because of the presence of great spinal tenderness, whereas this symptom is almost diagnostic of the absence of real spinal disease.

Painful diseases of the joints, especially in women, are not infrequently hysterical or neuromimetic. Many such cases have been reported. Taylor states, as the results of much carefully-guarded experience, that hundreds of lame people are walking about perfectly who do not know that they ought to limp, and that a much larger number are either limping and walking on crutches, or not walking at all, who have no affection whatever causing lameness.

Paget—and his experience accords with that of others—makes the hip and knee, among the joints, the most frequent seats of nervous mimicry as well as of real disease. According to him, mimicries in other joints are almost too rare for counting; and yet in my first case of this kind the pain was located in the shoulder. This case made a lasting impression. The patient was a young lady of nervous temperament, who came complaining of severe and continuous pain in the left shoulder. No history of injury was given. The pain was said to be rheumatic. Handling the arm and pressure round the joint caused extreme pain. No heat, no redness, no swelling were discoverable. The patient left me and went to a magnetic doctor, who entirely dispelled the disorder on her first visit by gently stroking the arm and shoulder. Another patient had been accidentally struck in the knee. No swelling, heat, or other signs of inflammation followed the accident, and did not afterward appear; but at intervals, for several years, she complained of severe pain in and around this joint. She would be for days, or it might be for weeks, without speaking of the pain; and then again she would complain almost incessantly, and would sometimes limp. These periods

¹ *Sensation and Pain*, by Charles Fayette Taylor, M. D.—a lecture delivered before the New York Academy of Sciences, March 21, 1881.

always corresponded with times of mental and physical depression, and the pain was evidently neuromimetic or hysterical.

The affection which has come down to us from ancient times under the name of *clavus hystericus* is an acute boring pain confined to a small point at the top of the head, and is sometimes described as resembling the pain which would be produced by driving a nail into the head; hence the term, from *clavus*, a nail. It may last for hours, days, or even weeks. Instead of *clavus hystericus*, *hemicrania*, occipital headache, or nape-aches may be present. On the whole, aches and pains of the head in hysterical cases are more likely to be localized to some point or area than to be general. Hysterical patients, however, not infrequently complain of constricting, contracting, or compressing sensations in the head.

In hysterical women the pulse is apt to be rapid, even sometimes twenty, thirty, to fifty pulsations to the minute above normal. The heart in these patients is irritable and prone to beat rapidly. One of Mitchell's cases is worthy of brief detail: A neurasthenic, hysterical woman, thirty-eight years old, when lying down had a heart-beat never less than 130 per minute. Exertion added twenty or thirty pulsations. Despite this irritability, however, the rhythm was good. Ovarian pressure and pressure along the spine would suddenly increase the heart-beats. Her temperature ranged from 95° in the morning to 100° or 101.5° F. in the evening, although she had no pulmonary or visceral trouble.

The high temperatures which have been observed in many cases of hysteria have been due to some form of shrewd fraud; but Briand¹ maintains with Gubler, Rigel, Dieulafoy, and others that the term hysterical fever is correct, and he describes three forms of the fever: (1) The slow continued fever of Briquet, characterized sometimes by simple acceleration of the pulse, without elevation of temperature; sometimes by a temperature rise, either with or without phenomena or accompanied by headache, thirst, and other symptoms; (2) a shorter form, always the result of a more or less active disturbance of the nervous system by terror, fear, chagrin, and like causes; (3) a form with intermittent febrile phenomena. Examples of the different forms are given. Debove² supports the view of the entity of the hysterical fever, citing cases—one a woman twenty-four years old who had, at intervals, marked fever, the temperature sometimes reaching 102½° to 104° F. Malaria and tuberculosis were excluded. Sulphate of quinia had no influence upon her attacks, but antipyrine reduced the temperature and her general condition improved. Debove has observed the temperature to rise from 1° to 2° F. by mere suggestion when the patient was in a somnambulistic state.

On the other hand, it has been claimed that a true hysterical fever never occurs or is extremely rare. Admitting this view, several explanations may be given of the rise of temperature observed. It may be due to intercurrent affections, as typhoid or intermittent fever, or some local inflammatory disorder. It may be secondary fever, the result of muscular effort or some similar cause. Lastly, and most probably, it may be due to ingenious fraud, as to friction of the bulb, pressure, or tapping

¹ *Gazette hebdomadaire*, quoted in *Med. News*, Dec. 1, 1883.

² *Ibid.*, quoted in *Med. News*, April 4, 1885.

with the finger, dipping the instrument into hot water, connivance with the nurse, etc. Du Castel¹ has reported a trick of this kind. An hysterical girl, convalescent from an attack of sore throat, displayed remarkable alternations of temperature. One day the thermometer reached 163.4° F.! By carefully watching the patient it was found she had learned the trick of lightly tapping the end of the thermometer, which caused the mercury to ascend as far as she wished. In the case of chronic hysterical insanity of which the details have been given the temperature in the axilla on several occasions reached 102°, 103°, and even 105° F.

Extreme states of pallor or blushing, sometimes in the extremities and at others in the face, are mentioned by Mitchell as among the vaso-motor disturbances of hysteria. Rosenthal gives a most interesting observation with reference to vaso-motor conditions in hysteria: the patient, a girl twenty-three years old, had epileptiform attacks, which were preceded by a subjective sensation of cold and discoloration of the hands and tips of the fingers. The hands became very pale, the tips of the fingers and nails of a deep blue; the patient experienced a disagreeable sensation of cold in the hands, and their temperature sank more than 3°, while the pulse dropped from 72 to 65 or 66. After the attack the temperature rose 2° higher than the normal condition; the fingers and nails became very red, and were the seat of an abundant perspiration; the pulse increased to 84 or 88. Other interesting symptoms were present.

Mitchell² has put on record three cases of hysteria in which was present unilateral increase in bulk at or near the menstrual period, and also at other seasons after emotional excitement. He does not give any opinion as to its nature, but believes that it is not a mere increase of areolar serum, and that it does not appear to resemble the vasal paralysis in which the leg throbs and exhibits a rise in temperature and tint. He is unable also to identify it with any form of lymph œdema which it resembles, for in this disorder there is more obvious œdema, and it is also quite permanent. Whatever the cause of the swelling, he believes that it is under the influence of the nervous system, and that it varies with the causes which produce analgesia or spasm. I have seen swelling of this kind in several cases, and have probably overlooked it in others. In one of my reported cases of hysterio-epilepsy it was a very marked symptom, coming and going, increasing and diminishing, with other symptoms.

Buzzard calls attention to the fact that in many cases belonging to the class of hysteria the epidermis, which has arrived at extraordinary thickness, apparently from disuse of the limbs, offers great resistance to the passage of electric currents. Under these circumstances a more than usual amount of care in thoroughly soaking and rubbing the skin, as well as in selecting the motor points, is necessary to avoid fallacies. Absence of reflex from the sole of the foot, according to the same authority, is a very constant symptom in hysterical paraplegia.

Some wasting does not negative the idea of hysteria, but this wasting is not associated with changing the electrical reaction.

Disturbance of the secretion of the urine is among the most frequent of the minor hysterical troubles, and has often been noted by writers upon

¹ *Revue de Thérapeutique méd.-chir.*, No xi., 1884.

² *American Journal of the Medical Sciences*, New Series, vol. lxxxviii., July, 1884, p. 94.

this subject since a very early date. Sydenham¹ says that of the "symptoms accompanying this disease, the most peculiar and general one is the making great quantities of urine as clear as rock-water, which upon diligent inquiry I find to be the distinguishing sign of those disorders which we call hypochondriac in men and hysteric in women. And I have sometimes observed in men that soon after having made urine of an amber color, being suddenly seized with some disturbance of mind, they made a large quantity of clear water, with a continued violent stream, and remained indisposed till the urine came to its former color, when the fit went off." This symptom shows itself as strikingly in the hysteria of the present day as in the age of Sydenham.

A complete anuria or ischuria is one of the older observations in hysteria. Laycock, Charcot, and many others have written at length on this subject. Finch² has published a curious case of complete anuria. The patient had various hysterical symptoms, including paroxysms with unconsciousness, contracture, also vomiting. Micturition and defecation were entirely suspended (?) from Dec. 24, 1877, to Feb. 22d of the following year. During a period of fifty-eight days paroxysms were frequent; but on using the catheter the bladder was always found empty. The probability of hysterical fraud is very great in this case. A few cases of hysterical retention of the urine in men have been reported.

Increase of the uterine and vaginal secretions is mentioned by Jolly as sometimes attributable to nervous influences in cases of hysteria. He mentions the case of a woman suffering from hysterical symptoms at the change of life whose disposition was decidedly depressed; though at times lively, particularly erotic. In this case simultaneously with tympanites appeared a thin, clear fluor albus. Local treatment with quiet had no decided effect, but it disappeared with the tympanites when the patient was excited by the visit of a sister who overwhelmed her with reproaches.

Hysterical vomiting of food sometimes persists for weeks; strangely enough, the patients usually appear to suffer little in consequence. Chambers believes that the articles swallowed do not all get into the stomach. The phenomena of rejection in these cases are similar to those of an œsophageal stricture; some of the matter swallowed is really retained, and therefore the patient will not starve as soon as might be supposed.

Two cases of simulated pregnancy by hysterical women have come under my observation. Cases are reported also in which hysteria simulated closely the process of natural labor, as one for instance, by Hodges.³ A woman said to be in the fifth month of pregnancy engaged him to attend her at term. Four months afterward he was sent for, the patient having severe pains, supposing herself to be in labor. On examination, however, a tumor present turned out to be the bladder distended and prolapsed. Sparks⁴ reports the case of a young married woman who had the symptoms of the third stage of labor, the case being purely hysterical.

Walker⁵ reports a group of hysterical symptoms closely simulating the prodromes of puerperal eclampsia. The patient, a married woman only

⁵ *Arch. of Medicine*, New York, 1883, x. 85-88.

eighteen years old, when pregnant six months lifted a tub of water, rupturing the membranes. In the eighth month, after she had remained in bed three days, she began to complain of severe headache; soon she said she was blind; the pupils of the eye were neither dilated nor contracted, and responded sluggishly to light. Ophthalmoscopic examination gave negative results, but she did not flinch from the light of the mirror. Temperature, pulse, and respiration were about normal. The urine contained no albumen. She recovered her sight in twelve hours, and had no continuing trouble.

Paget mentions cases of phantom tumor occurring in the calf, thigh, and breast. These phantoms shift from one place to another, or disappear when the muscles are relaxed by anæsthetics or otherwise. The nervous mimicry of aneurisms (of Paget) are what Laycock and others treat of as pulsations. They are most frequent in the carotid artery and abdominal aorta. Of imitations of cancer it need only be said that the average hysterical female suspects every lump in the breast and elsewhere to be a cancer.

Mitchell mentions certain peculiar symptoms quite common among hysterical women, but which also occur, but more rarely, among men. When falling asleep these patients have something like an aura rising from the feet and going up toward the head. One patient had an aura which passed upward from his feet, and when it had reached his head he felt what he described as an explosion. Another had a sensation as though something was about to happen, but no distinct ascending aura. If he roused himself in time, he could by turning over release himself from the sensation and break the chain of morbid events. At the close of the attack he had a noise in his head—something like the sound of a bell which had been struck once. Other patients when going to sleep have constant sounds, faint usually and rarely loud and without a feeling of terror. Most of the patients were women worn out or tired out and hysterical.

Sometimes hysterical women awake with numbness and tingling, which rapidly passes away or yields to a little surface friction. Some persons who have in a measure recovered from hemiplegia of organic origin are liable to awake out of sleep with a numbness and lessening of power on the side once palsied. Palpitation of the heart, vertigo, and a certain fear of a respiratory character are among the milder forms of trouble which Mitchell mentions as haunting the sleep of nervous or hysterical women.

Under hysteria some of the affections, more common among men than women, known as railway brain, railway spine, etc., may be classified. These disorders might be termed traumatic hysteria. The amount of money that has been paid out by corporations, beneficial societies, or individuals because of suits or threatened suits for damages in cases of railway or other accidents is something almost incredible. At least two classes of cases, besides those of recognizable gross lesion, are to be found in the ranks of those claiming such damages. These are first the bogus cases or malingerers, and secondly cases of nervous mimicry. An hysterical individual who has been in a railway collision, or has been the victim of an accident for which somebody else may possibly be made responsible, may deliberately practise fraud, or he may con-

sciously or unconsciously imitate or exaggerate real symptoms of serious import. Sometimes there may be in the same case a mingling of real and of simulated or of neuromimetic disorders. As long as a claim of damages in this class of cases exists, great care should be taken in making a diagnosis. The neuromimetic cases, however, do occur, particularly in the hysterical and neurasthenic, without any reference to litigation.

A lady fell off her chair backward. She was not rendered unconscious, but became nervous, and began to have considerable pain and soreness in the sacral region and about the right sacro-iliac juncture. She had no palsy, nor spasm, nor anæsthesia, nor paræsthesia, and had no difficulty in her bladder, but nevertheless was helpless in bed for many weeks, supposing herself unable to stand. She recovered promptly, under treatment with electricity, as soon as a favorable prognosis was given in a very positive manner.

A man fell on the ice and struck his back, but was able to go on with his usual occupation, although complaining of his limbs. Two months afterward, while recovering from typhoid fever, he fell from a chair, and was unable to raise himself, and found that he had lost control of his legs and arms. During the attack he was not unconscious. He was bed-ridden for two months, but did not lose control of his bladder and bowels. He was put on his feet by a little treatment and much encouragement.

A woman was badly pushed about while riding in a street-car by the car being thrown off the track. She miscarried in about six weeks, flooding a good deal after injury to the time of miscarriage. Later, spinal symptoms began. She had extensive pain and tenderness at the lower end of the spine. She sometimes fainted. Examination revealed general spinal tenderness, much more marked in the sacro-coccygeal region. She was pale, anæmic, and neurasthenic. She brought suit against the railway company for damages, which were very properly awarded, as the miscarriage, hemorrhage, and consequent anæmia were without doubt the result of an accident for which she was in no wise responsible. Some organic spinal-cord disease, however, was supposed to exist, the chief foundation for this view being the extreme spinal tenderness, which was hysterical.

Finally, some hysterical cases present a succession of local hysterical phenomena following each other more or less rapidly. One symptom seems to take possession of the patient for the time being, but when relieved or cured of this, suddenly a new manifestation occurs. A new figure appears upon the scene, or perhaps I might better say a new actor treads the boards. Even in these cases, however, it would be difficult to say that the phenomena are really simulated. They are rather induced, and get partly beyond the patient's will.

A remarkable case of this kind is well known at the Philadelphia Polyclinic and College for Graduates in Medicine. She is sometimes facetiously spoken of as the "Polyclinic Case," because she has done duty at almost every clinical service connected with the institution. The case has been reported several times: the fullest report is that given by Harlan.¹ The patient was taken sick in September with sore throat, and was confined to the house for about two weeks. She was attended by S. Solis

¹ *Transactions of the Amer. Ophthalmological Soc.*, 20th annual meeting, 1884, 649.

Cohen. There was difficulty in swallowing, and some regurgitation of food. At the same time she had weakness of sight in the right eye. Later, huskiness of voice came on, and soon complete aphonia. Her voice recovered, and she then had what appeared to be pleuro-pneumonia. During the attack her arms became partially paralyzed. She complained of numbness down her legs and in her feet.

Before these symptoms had disappeared twitchings of the muscles of the face set in, most marked on the right side. The face improved, but in two days she had complete spasmodic torticollis of the left side. One pole of a magnet was placed in front of the ear, and the other along the face; and under this treatment in a week the spasm ceased entirely.

In a short time she complained of various troubles of vision and a fixed dilatation of the pupil. Homonymous diplopia appeared. Reading power of the right eye was soon lost. The pupil was slightly dilated, and reacted imperfectly to light. She had distressing blepharospasm on the right side and slight twitchings on the left. Two months later a central scotoma appeared, and eventually her right eye became entirely blind except to light. The pupil was widely dilated and fixed, and the spasm became more violent and extended to the face and neck. The sight was tested by Harlan by placing a weak convex lens in front of the blind eye, and one too strong to read through in front of the sound eye, when it was found that she read without any difficulty. The use of the magnet was continued by Cohen. Blepharospasm and dilatation of the pupil improved. She, however, had an attack of conjunctivitis in the left eye, and again got worse in all her eye symptoms. A perfect imitation of the magnet was made of wood with iron tips. Under this imitation magnet the pupil recovered its size and twitching of the face and eyelids ceased.

The next campaign was precipitated by a fall. She claimed that she had dislocated her elbow-joint; she was treated for dislocation by a physician, and discharged with an arm stiff at the elbow. A wooden magnet was applied to the arm, the spasm relaxed, and the dislocation disappeared.

This ends Harlan's report of the case, and I had thought that this patient's Iliad of woes was also ended; but I have just been informed by J. Solis Cohen and his brother that she has again come under their care. The latter was sent for, and found the patient seemingly choking to death. The right chest was fixed; there was marked dyspnoea; respiration 76 per minute; her expectoration was profuse; she had hyper-resonance of the apex, and loud mucous râles were heard. At last accounts she was again recovering.

This patient's train of symptoms began with what appeared to be diphtheria. The fact that she had some real regurgitation would seem to be strong evidence that she had some form of throat paralysis following diphtheria. She was of neurotic temperament. From the age of seven until ten years she had had fits of some kind about every four weeks. Because of her sore throat and subsequent real or seeming paralytic condition she came to the Polyclinic, where she was an object of interest and considerable attention, having been talked about and lectured upon to the classes in attendance. Whether her first symptoms were or were not hysterical, those which succeeded were demonstrably of this character. Fre-

quently some real disease is the starting-point of a train of hysterical disorders.

DURATION AND COURSE.—Hysteria is pre-eminently a chronic disease; in the majority of cases it lasts at least for years. Its symptoms may be prolonged in various ways. Sometimes one grave hysterical disorder, as hysterical paralysis, persists for years. In other cases one set of symptoms will be supplanted by others, and these by still others, and so on until the whole round of hysterical phenomena appears in succession.

Deceptive remissions in hysterical symptoms often mislead the unwary practitioner. Cures are sometimes claimed where simply a change in the character of the phenomena has taken place. Without doubt, some cases of hysteria are curable; equally, without doubt, many cases are not permanently cured. It is a disease in which it is unsafe to claim a conquest too soon. In uncomplicated cases of hysteria the disorder often abates slowly but surely as age advances. As a rule, the longevity of hysterical patients is not much affected by the disorder.

COMPLICATIONS.—We should not treat a nervous case occurring in a woman or a man as hysterical simply because it is obscure and mysterious. Unless, after the most careful examination, we are able by exclusion or by the presence of certain positive symptoms to arrive at the diagnosis of hysteria, it is far better to withhold an opinion or to continue probing for organic disease. I can recall five cases in which the diagnosis of hysteria was made, and in which death resulted in a short time. One of these was a case of uræmia with convulsions, two were cases of acute mania, another proved to be a brain abscess, and the fifth a brain tumor. Hughes Bennett¹ has reported a case of cerebral tumor with symptoms simulating hysteria in which the diagnosis of the true nature of the disease was not made out during life. The patient was a young lady of sixteen at the time of her death. Her family history was decidedly neurotic. She was precocious both mentally and physically, was mischievous and destructive, sentimental and romantic; she had abnormal sexual passions. She had a sudden attack of total blindness, with equally sudden recovery of sight some ten days afterward. Sudden loss of sight occurred a second time, and deafness with restoration of hearing, loss of power in her lower limbs, and total blindness, deafness, and paraplegia. Severe constant headaches were absent, as were also ptosis, diplopia, facial or lingual paralysis, convulsions with unconsciousness, vomiting, wasting, and abnormal ophthalmoscopic appearances. She had attacks of laughing, crying, and throwing herself about. Her appearance and character were eminently suggestive of hysteria. The patient died, and on post-mortem examination a tumor about the size and shape of a hen's egg was found in the medullary substance of the middle lobe of the right hemisphere.

The association of hysteria with real and very severe spinal traumatism partially misled me in the case of a middle-aged man who had been injured in a runaway accident, and who sustained a fracture of one of the upper dorsal vertebræ, probably of the spines or posterior arch. This was followed by paralysis, atrophy of the muscles, contractures, changed reactions, bladder symptoms, bed-sores, and anæsthesia. The upper extremities were also affected. Marked mental changes were present,

¹ *Brain*, April, 1878.

the man being almost insanely hysterical. The diagnosis was fracture, followed by compression myelitis, with descending motor and ascending sensory degeneration. An unfavorable prognosis was given. He left the hospital and went to another, and finally went home, where he was treated with a faradic battery. He gradually improved, and is now on his feet, although not well. In this case there was organic disease and also much hysteria.

Seguin¹ holds that (1) many hysterical symptoms may occur in diseases of the spinal cord and brain; (2) in diseases of the spinal cord these diseases appear merely as a matter of coincidence; (3) in cases of cerebral disease the hysterical symptoms have a deeper significance, being in relation to the hemisphere injured. He collects, as illustrative of the propositions that hysterical symptoms will present themselves in persons suffering from organic disease of the nervous system, the following cases of organic spinal disease: One case of left hemiplegia with paresis of the right limbs, which proved after death to be extensive central myelitis, with formation of cavities in the cord; two cases of posterior spinal sclerosis, two of disseminated sclerosis, and one of sclerosis of the lateral column. In some of these cases the organic disease was wholly overlooked. Sixteen cases of organic disease of the brain accompanied by marked hysterical manifestations are also given: 9 of left hemiplegia; 2 of right hemiplegia with aphasia; 1 of left alternating with right hemiplegia; 1 of hemichorea with paresis; 1 of double hemiplegia; and 2 of general paresis. It is remarkable and of interest, in connection with other unilateral phenomena of hysteria, that emotional symptoms were present in 14 cases of left hemiplegia and in only 2 of right.

Among the important conclusions of this paper are the following: "1. In typical hysteria the emotional symptoms are the most prominent, and according to many authors the most characteristic. In all the cases of cerebral disease related there were undue emotional manifestations or emotional movements not duly controlled. 2. In typical hysteria many of the objective phenomena are almost always shown on the left side of the body, and we may consequently feel sure that in these cases the right hemisphere is disordered. In nearly all of the above sixteen cases the right hemisphere was the seat of organic disease, and the symptoms were on the left side of the body."

The possibility of the occurrence of hysteria in the course of acute diseases, particularly fevers, is often overlooked. Its occurrence sometimes misleads the doctor with reference to prognosis. Such manifestations are particularly apt to occur in emotional children. A young girl suffering from a moderately severe attack of follicular tonsillitis, with high fever, suddenly awoke during the night and passed into an hysterical convulsion which greatly alarmed her parents. Her fingers, hands, and arms twitched and worked convulsively. She had fits of laughing and shouting, and was for a short time in a state of ecstasy or trance. Once before this she had had a similar but slighter seizure, during the course of an ephemeral fever.

Among other complications of hysteria which have been noted by different observers are apoplexy, disease of the spleen, mania-a-potu, heart

¹ *Op. cit.*

disease, and spinal caries, and among affections alluded to by competent observers as simulated by hysteria are secondary syphilis, phthisis, tetanus, strychnia-poisoning, peritonitis, angina pectoris, and cardiac dyspnoea.

DIAGNOSIS.—Buzzard¹ significantly remarks that you cannot cure a case of hysteria as long as you have any serious doubt about its nature; and, on the other hand, if you are able to be quite sure on this point, and are prepared to act with sufficient energy, there are few cases that will not yield to treatment. The importance of a correct diagnosis is a trite topic, but in no affection is it of more consequence than in hysteria, that disorder which, although itself curable, may, as has been abundantly shown, imitate the most incurable and fatal of diseases.

A few remarks with reference to the methods of examining hysterical patients will be here in place. Success on the part of the physician will often depend upon his quickness of perception and ability to seize passing symptoms. It is often extremely difficult to determine whether hysterical patients are or are not shamming or how far they are shamming. The shrewdness and watchfulness which such patients sometimes exercise in resisting the physician's attempts to arrive at a diagnosis should be borne in mind. A consistent method of procedure, one which never betrays any lack of confidence, should be adopted. "Trifles light as air" will sometimes decide, a single expression or a trivial sign clinching the diagnosis. On the other hand, the most elaborate and painstaking investigation will be frequently required.

The physician should carefully guard against making a diagnosis according to preconceived views. On the whole, the general practitioner is more likely to err on the side of diagnosing organic disease where it does not exist; the specialist in too quickly assigning hysteria where organic disease is present, or in failing to determine the association of hysteria and organic disease in the same case.

Special expedients may sometimes be resorted to in the course of an examination. Not a few hysterical symptoms require for their continuance that the patient's mind shall be centred on the manifestations. If, therefore, the attention can, without arousing suspicions, be directed to something else during the examination, the disappearance of the particular hysterical symptom may clear away all obscurity. In a case reported by Seguin,² in which staggering was a prominent symptom, the patient was placed in the middle of the room and directed to look at the ceiling to see if he could make out certain fine marks; he stood perfectly well without any unsteadiness. In the case of a boy eleven years old whose chief symptoms were hysterical paralysis with contracture of the lower extremities, great hyperæsthesia of the feet, and a tremor involving both the upper and lower extremities, and sometimes the head, I directed him, as if to bring out some point, to hold one arm above his head and at the same time fix his attention on the foot of the opposite side. The tremor in the upper extremities, which had been most marked, entirely disappeared. This experiment was varied, the result being the same.

The method adopted in the cases supposed to be phthisis, but which proved to be hysterical, which has already been alluded to under the

¹ *Clinical Lectures on Diseases of the Nervous System*, by Thomas Buzzard, M. D., Philada., 1882.

² *Op. cit.*

head of hysterical or nervous breathing, is worthy of note. The patients, it will be recalled, could not be induced to draw a long breath until the plan was adopted of having them count twenty without stopping, when the lungs expanded and the diagnosis was clear.

It is important to know whether or not children are of this hysterical tendency or are likely, sooner or later in life, to develop some forms of this disorder. In children as well as in adults the hysterical diathesis will be indicated by that peculiar mobility of the nervous system, which has been referred to under Etiology. It is chiefly by psychical manifestations that the determination will be made. These are often of mild degree and of irregular appearance. Undue emotionality under slight exciting cause, a tendency to simulation and to exaggeration of real conditions, inconsistency in likes and dislikes, and great sensibility to passing impressions, are among these indications. Children of hysterical diathesis are sometimes, although by no means always, precocious mentally, but not a few cases of apparent precocity are rather examples of an effort to attract attention, which is always present in individuals of this temperament.

It is also important, as urged by Allbutt,¹ to make a distinction between hysterical patients and neurotic subjects, often incorrectly classed as hysterical. Many cases of genuine malady and suffering are contemptuously thrown aside as hysteric. Allbutt regards some of these neurotic patients as almost the best people in this wicked world. Although, however, this author's righteous wrath against the too frequent diagnosis of hysteria, hysterical pain, hysterical spine, etc. is entirely justifiable, he errs a little on the other side.

Hysteria and neurasthenia are often confounded, and, while both conditions may exist in the same case, just as certainly one may be present without the other. The points of differential diagnosis as given by Beard² are sufficient for practical purposes. They are the following: In neurasthenia convulsions or paroxysms are absent; in hysteria they are among the most common features. In neurasthenia globus hystericus and anæsthesia of the epiglottis are absent, ovarian tenderness is not common, and attacks of anæsthesia are not frequent and have little permanency; in hysteria globus hystericus, anæsthesia of the epiglottis, ovarian tenderness, and attacks of general or local anæsthesia are all marked phenomena. The symptoms of neurasthenia are moderate, quiet, subdued, passive; those of hysteria are acute, intense, violent, positive. Neurasthenia may occur in well-balanced intellectual organizations; hysteria is usually associated with great emotional activity and unbalanced mental organization. Neurasthenia is common in males, although more common in females; hysteria is rare in males. Neurasthenia is always associated with physical debility; hysteria in the mental or psychical form occurs in those who are in perfect physical health. Neurasthenia never recovers suddenly, but always gradually and under the combined influences of hygiene and objective treatment; hysteria may recover suddenly and under purely emotional treatment.

¹ *On Visceral Neuroses, being the Gulstonian Lectures on Neuralgia of the Stomach and Allied Disorders*, delivered at Royal College of Physicians, March, 1884, by T. Clifford Allbutt, M. A., M. D. Cantab., F. R. S., Philada., 1884.

² *Op. cit.*

An affection termed general nervousness has been described by Mitchell. It does not seem to be strictly a neurasthenia, nor does it always occur in hysterical individuals. These cases are sometimes "more or less neurasthenic people, easily tired in brain or body; but others are merely tremulous, nervous folks, easily agitated, over-sensitive, emotional, and timid." It is sometimes an inheritance; sometimes it results from the misuse of alcohol, tobacco, tea or coffee. Usually, it is developed slowly; occasionally, however, it arises in a moment. Thus, Mitchell mentions the case of a healthy girl who fell suddenly into a state of general nervousness owing to the fall of a house-wall. General nervousness is to be distinguished from hysteria, into which it sometimes merges, only by the absence of the mental perversions and the special motor, sensory, vasomotor, and visceral disorders peculiar to the latter.

The differential diagnosis of hysteria and hypochondria, or what is better termed hypochondriacal melancholia, is often, apparently at least, somewhat difficult. Formerly, it was somewhat the fashion to regard hysteria in the male as hypochondria; but this view has nothing to support it. Hypochondria and hysteria, as neurasthenia and hysteria, are sometimes united in the same subject; one sometimes begets the other, but they have certain points of distinction. Hypochondria more frequently passes into real organic disease than does hysteria; it is more frequently associated with organic disease than is hysteria. Hypochondria is in the majority of cases a true insanity, while hysteria can only be regarded as such in the special instances which have been discussed. In hypochondria the individual's thoughts are centred upon some supposed disease until a true delusional condition is developed; this does not often occur in hysteria. Hypochondria is seen with as great a frequency in the male as in the female, while hysteria prevails much more largely in the female sex. In typical hypochondria more readily than in hysteria the patient may be led from one set of symptoms to another, the particulars of which he will detail in obedience to questions that are put to him, these symptoms not unusually partaking of the absurd and impossible. In hypochondria are absent those distinctive symptoms which in nearly all cases of hysteria appear in greater or less number, such as convulsions, paralysis, contracture, aphonia, hysterical joints, and the like. In hypochondria is present the groundless fear of disease without these outward manifestations of disease. The symptoms of hypochondria, as a rule, but not invariably, are less likely to change or abate than those of hysteria.

It is often of moment to be able to distinguish between two such well-marked affections as common acute mania and hysterical mania. In acute mania the disorder usually comes on gradually; in hysterical mania the outbreak of excitement is generally sudden, although prodromic manifestations are sometimes present. This point of difference is not one to be absolutely depended upon. In acute mania incoherence and delusions or delusional states are genuine phenomena; in hysterical mania delusional conditions, often of an hallucinatory character, may be present, but they are likely to be of a peculiar character. Frequently, for instance, such patients see, or say that they see, rats, toads, spiders, and strange beasts. These delusions have the appearance of being affected in many cases; very often they are fantastical, and sometimes at least they are spurious or simulated. In hysterical mania such phe-

nomena as obstinate mutism, aphonia, pseudo-coma, ecstasy, catalepsy, and trance often occur, but they are usually absent in the history of cases of acute mania. In acute mania under the influence of excitement or delusion the patients may take their own lives: they may starve or kill themselves violently; in hysterical mania suicide will be threatened or apparently attempted, but the attempts are not genuine as a rule; they are rather acts of deception. In acute mania the patients often become much reduced and emaciated; in hysterical mania in general, considering the amount of mental and motor excitement through which the individuals pass, their nutrition remains good. In acute mania sleeplessness is common, persistent, and depressing; in hysterical mania usually a fair amount of sleep will be obtained in twenty-four hours. In many cases of hysterical mania the patients have their worst attacks early in the morning after a good night's rest. Acute mania under judicious treatment and management may gradually recover; sometimes, however, it ends fatally: this is especially likely to occur if the physician supposes the case to be simply hysterical and acts accordingly. Hysterical mania seldom has a serious termination unless through accident or complication.

In order to make the diagnosis of purposive hysterical attacks watchfulness on the part of the physician will often suffice. Such patients can frequently be detected slyly watching the physician or others. Threats or the actual use of harsh measures will sometimes serve for diagnostic ends, although the greatest care should be exercised in using such methods in order that injustice be not done.

In uræmia, as in true epilepsy, the convulsion is marked and the condition of unconsciousness is usually profound. An examination of the urine for albumen, and the presence of symptoms, such as dropsical effusion, which point to disorder of the kidneys, will also assist.

Hysterical paralysis in the form of monoplegia or hemiplegia must sometimes be distinguished from such organic conditions as cerebral hemorrhage, embolism or thrombosis, tumor, abscess, or meningitis (cerebral syphilis).

When the question is between hysteria and paralysis from coarse brain disease, as hemorrhage, embolism, etc., the history is of great importance. The hysterical case usually has had previous special hysterical manifestations. The palsy may be the last of several attacks, the patient having entirely recovered from other attacks. In an organic case, if previously attacked, the patient has usually made an incomplete recovery; the history is of a succession of attacks, each of which leaves the patient worse. In cerebral syphilis it happens sometimes that coming and going paralysis occur; but the improvement in these cases is generally directly traceable to specific treatment. Partial recoveries take place in embolism, thrombosis, hemorrhage, etc. when the lesion has been of a limited character, but the improvement is scarcely ever sufficient to enable the patient to be classed as recovered. The exciting cause of hysterical and organic cases of paralysis is different. While in hysterical paralysis sudden fright, anxiety, anger, or great emotion is frequently the exciting cause, such psychical cause is most commonly not to be traced as the factor immediately concerned in the production of the organic paralysis. In the organic paralysis an apoplectic or apoplectiform attack of a peculiar kind has usually occurred. In cerebral hemorrhage or embolism the

patient suddenly loses consciousness, and certain peculiar pulse, temperature, and respiration phenomena occur. The patient usually remains in a state of complete unconsciousness for a greater or less period. In hysteria the conditions are different. A state of pseudo-coma may sometimes be present, but the temperature, pulse, and respiration will not be affected as in the organic case.

Hysterical monoplegia or hemiplegia, as a rule, is not as complete as that of organic origin, and is nearly always accompanied by some loss of sensation. The face usually escapes entirely. In organic palsy the face is generally less severely and less permanently affected than the limbs, but paresis is commonly present in some degree. Hysterical palsies are more likely to occur upon the left than upon the right side. Embolism is well known to occur most frequently in the left middle cerebral artery, thus giving the palsies upon the right. In hemorrhage and thrombosis the tendency is perhaps almost equal for the two sides. Some of these and other points of distinction between organic and hysterical palsies have been given incidentally under Symptomatology.

In organic hemiplegia aphasia is more likely to occur than in hysterical cases; and acute bed-sores and wasting of the limbs, with contractures, are conditions frequently present as distressing sequelæ. Such is not the rule in hysterical cases, for while there may be wasting of the limbs from disuse and hysterical contractures, bed-sores are seldom present, and the wasting and contractures do not appear so insidiously, nor progressively advance to painful permanent conditions, as in the organic cases. Mitchell mentions the fact that in palsies from nerve wounds feeling is apt to come back first, motion last; while in the hysterical the gain in the power of motion may go on to full recovery, while the sense of feeling remains as it was at the beginning of treatment. This point of course would help only in cases where both sensory and motor loss are present.

The examination of an hysterically palsied limb, if conducted with care, may often bring out the suppressed power of the patient. Practising the duplicated, active Swedish movements on such a limb will sometimes coax resistance from the patient. As already stated, electro-contraction is retained in hysterical cases.

The disorders from which it may be necessary to diagnosticate hysterical paraplegia are spinal congestion, subacute generalized myelitis of the anterior horns (chronic atrophic spinal paralysis of Duchenne), diffused myelitis, acute ascending paralysis, spinal hemorrhage, spinal tumor, posterior spinal sclerosis or locomotor ataxy, lateral sclerosis or spasmodic tabes, multiple cerebro-spinal sclerosis, and spinal caries.

In spinal congestion the patients come with a history that after exposure they have lost the use of their lower limbs, and sometimes of the upper. Heaviness and pain in the back are complained of, and also more or less pain from lying on the back. Numbness in the legs and other disturbances of sensation are also present. The paralysis may be almost altogether complete. Such patients exhibit evidences of the involvement of the whole cord, but not a complete destructive involvement. A colored woman, age unknown, had been in her ordinary health until Nov. 24, 1884. At this time, while washing, she noticed swelling of the feet, which soon became painful, and finally associated with loss of power. She had also a girdling sensation about the abdomen and pain in the back. She was

admitted to the hospital one week later, at which time there was retention of the urine and feces. She had some soreness and tenderness of the epigastrium. She complained of dyspnoea, which was apparently independent of any pulmonary trouble. It was necessary to use the catheter for one week, by which time control of the bladder had been regained. The bowels were regulated by purgatives. She was given large doses of ergot and bromide and iodide of potassium, and slowly improved, and after a time was able to get out of bed and walk with the aid of a chair. An examination at the time showed that the girdling pain had disappeared. There was distinct loss of sensation. Testing the farado-contractility, it was found that in the right leg the flexors only responded to the slowly-interrupted current, while in the left both flexors and extensors responded to the interrupted current. In both limbs with the galvanic current the flexors responded to twenty cells, while the extensors responded to fifty cells. She gradually improved, and was able to leave after having been in the hospital three months.

The diagnosis of subacute myelitis of the anterior horns from hysterical paraplegia is often of vital importance. "A young woman," says Bennett,¹ "suddenly or gradually becomes paralyzed in the lower extremities. This may in a few days, weeks, or months become complete or may remain partial. There is no loss of sensation, no muscular rigidity, no cerebral disturbances, nor any general affection of the bladder or rectum. The patient's general health may be robust or it may be delicate. She may be of emotional and hysterical temperament, or, on the contrary, of a calm and well-balanced disposition. At first there is no muscular wasting, but as the disease becomes chronic the limbs may or may not diminish in size. The entire extremity may be affected or only certain groups of muscles. Finally, the disease may partially or entirely recover, or remain almost unchanged for years." This is a fair general picture of either disease.

Two facts are often overlooked in this connection: first, that poliomyelitis is just as liable to occur in the hysterical as in the other class; and, secondly, that the symptoms of hysterical paraplegia and poliomyelitis may go hand in hand.

The history is different in the two affections. Frequent attacks of paralysis in connection with hysterical symptoms are very suggestive, although not always positive. In poliomyelitis the disease may come on with diarrhoea and fever; often it comes on with vomiting and pain. The patellar reflex is retained, often exaggerated, and rarely lost, in hysteria, while it is usually lost in poliomyelitis. Electro-muscular contractility is often normal in hysterical paralysis, although it is sometimes slightly diminished quantitatively to both faradism and galvanism: the various muscles of one limb respond about equally to electricity: there are no reactions of degeneration in hysterical paralysis as in poliomyelitis. In poliomyelitis reactions of degeneration are one of the most striking features. The cutaneous plantar reflex is impaired in hysterical paraplegia; bed-sores are usually absent, as are also acute trophic eschars and the nail-markings present both in generalized subacute myelitis and diffused myelitis. True muscular atrophy is also wanting in hysterical paraplegia, although the limbs may be lean and wasted from the original

¹ *Lancet*, vol. ii. p. 842, November, 1882.

thinness of the patient or from disuse. The temperature of the limbs is usually good. There is no blueness nor redness of the limbs, nor are the bowels or bladder uncomfortably affected.

Buzzard¹ gives two diagrams (Figs. 16 and 17), which I have reproduced. They are drawn from photographs. They show two pairs of feet, which have a certain superficial resemblance. In each the inner border is drawn up into the position of a not severe varus. They are the feet of two young women who were in the hospital at

FIG. 16.

FIG. 17.

the same time. A (Fig. 16), really a case of acute myelitis, had been treated as a case of hysteria; and B (Fig. 17), really a case of hysteria, came in as a paralytic. In these cases the results of examination into the state of the electrical response and of the patellar-tendon reflex was sufficient to make a diagnosis clear. In the organic case the electrical reactions were abnormal and the patellar-tendon reflex was abolished. These conditions were not present in the hysterical case.

The diagnosis of hysterical paraplegia from diffused myelitis is governed practically by the same rules which serve in subacute myelitis of the anterior horns, with some additional points. In diffused myelitis, in addition to the motor, trophic, vaso-motor, electrical, and reflex disorders of myelitis of the anterior horns, affections of sensibility from involvement of the sensory regions of the cord will also be present. Anæsthesia and paræsthesia will be present.

Acute ascending paralysis, the so-called Landry's paralysis, particularly when it runs a variable course, might be mistaken sometimes for hysterical paralysis. In one instance I saw a fatal case of Landry's paralysis which had been supposed to be hysterical until a few hours before death. In Landry's paralysis, however, the swiftly ascending character of the disorder is usually so well marked as to lead easily to the diagnosis. In Landry's paralysis the loss of power begins first in the legs, but soon becomes more pronounced, and passes to the arms, and in the worst cases swallowing and respiration become affected.

Spinal hemorrhage and spinal tumors, giving rise to paralysis, may be mistaken for hysterical paralysis, partly because of the contractures. Reactions of degenerations are usually features of this form of organic paralysis. The contractures of hysterical paralysis can be promptly

¹ *Clin. Lectures on Diseases of the Nervous System*, London, 1882.

relieved by deep, strong pressure along supplying nerve-trunks; this cannot be accomplished in the organic cases. Severe localized pains in the limbs, sometimes radiating from the spinal column, are present in the organic cases. Pain may be complained of by the hysterical patient, but close examination will show that it is not of the same character, either as regards severity or duration.

Hysterical locomotor ataxy is usually readily distinguished from posterior spinal sclerosis, although the phenomena are apparently more marked and more peculiar than those exhibited as the result of organic changes. Hysterical ataxic patients often show an extraordinary inability to balance their movements, this want of co-ordinating power being observed even in the neck and trunk, as well as the limbs. In hysterical cases a certain amount of palsy, often of an irregular type, is more likely to be associated with the ataxia than in the structural cases. The knee-jerk, so commonly absent in true posterior spinal sclerosis that its absence has come to be regarded as almost a pathognomonic symptom of this affection, in hysterical motor ataxy is present and exaggerated. In hysterical locomotor ataxy other well-marked symptoms of general hysteria, such as hysterical convulsions, aphonia, etc., are present.

In the diagnosis of spastic spinal paralysis from hysterical paraplegia great difficulties will sometimes arise. A complete history of the case is of the utmost importance in coming to a conclusion. If the case be hysterical, usually some account of decided hysterical manifestation, such as aphonia, sudden loss and return of sight, hysterical seizures, etc., can be had. Althaus holds that a dynamometer which he has had constructed for measuring the force of the lower extremities will, at least in a certain number of cases, enable us to distinguish between the functional and spinal form of spastic paralysis. In the former, although the patient may be unable to walk, the dynamometer often exhibits a considerable degree of muscular power; while in the latter, more especially where the disease is somewhat advanced, the index of the instrument will only indicate 20° or 30° in place of 140° or 160° , and occasionally will make no excursion at all.

The diagnosis of multiple cerebro-spinal sclerosis from hysteria occasionally offers some difficulties. Jolly goes so far as to say that it can only with certainty be diagnosticated in some cases in its later stages and by the final issue—cases in which the paralytic phenomena frequently alter their position, in which paroxysmal exacerbations and as sudden ameliorations take place, and convulsive attacks and disturbances of consciousness of a like complicated nature as in hysteria are met with. Disorders of deglutition and articulation, also characteristic of multiple cerebro-spinal sclerosis, are now and again observed in the hysterical. Recently, through the kindness of J. Solis Cohen, I saw at the German Hospital in Philadelphia a patient about whom there was for a time some doubt as to whether the peculiar tremor from which he suffered was hysterical or sclerotic. At rest and unobserved, he was usually quiet, but as soon as attention was directed to him the tremor would begin, at first in the limbs, but soon also in the head and trunk. If while under observation he attempted any movement with his hands or feet, the tremor would become violent, and if the effort was persisted in it would become convulsive in character. The effort to take a glass of water threw him into

such violent spasms as to cause the water to be splashed in all directions. The fact that this patient was a quiet, phlegmatic man of middle age, that his troubles had come on slowly and had progressively increased, that tremor of the head and trunk was present, that cramps or tonic spasms of the limbs came and went, indicated the existence of disseminated sclerosis. The knee-jerk was much exaggerated, taps upon the patellar tendon causing decided movement; when continued, the leg would be thrown into violent spasm.

Spondylitis, or caries of the vertebræ, is sometimes difficult to distinguish from hysterical paraplegia or hysterical paraplegia from it, or both may be present in the same case. Likewise, painful paraplegia from cancer or sarcoma of the vertebræ may offer some difficulties. A woman aged forty-four when two years old had a fall, which was followed by disease of the spine, and has resulted in the characteristic deformity of Pott's disease. She was apparently well, able to do ordinary work, until about five years before she came under observation, when her legs began to feel heavy and numb, and with this were some pain and slight loss of power. These symptoms increased, and in three months were followed by a total loss of power in the lower extremity. She was admitted to the hospital, and for about three years was unable to move the legs. She went round the wards in a wheeled chair. The diagnosis was made of spondylitis, curvature, and paralysis and sensory disorders depending on compression myelitis, and it was supposed she was beyond the reach of remedies. One day one of the resident physicians gave her a simple digestant or carminative, soon after which she got up and walked, and has been walking ever since. She attributes her cure entirely to this medicine.

What is the lesson to be learned from this case? It is, in the first place, not to consider a patient doomed until you have made a careful examination. There can be much incurvation of the spine without sufficient compression to cause complete paralysis. In this patient organic disease was associated with an hysterical or neuromimetic condition. This woman had disease of the vertebræ, the active symptoms of which had subsided. The vertebral column had assumed a certain shape, and the cord had adjusted itself to this new position, yet for a long time she was considered incurable from the fact that the conjunction of a real and a mimetic disorder was overlooked.

Another patient aged twenty-seven had whooping cough, which lasted six weeks, and was followed by severe pain in the back. For this she consulted various physicians, being treated for Pott's disease and spinal irritation. She, however, continued to grow worse, and every jar and twist gave severe pain. At this time she had lost much flesh, had pain in her back and elsewhere, and was subject to numerous and violent spasms. When first seen by the physician who consulted me she was complaining of pains in her legs, hips, and left shoulder, which she considered rheumatic, and with pain in the abdomen. Examination of the back with the patient on her side showed a slight prominence over the position of the first or second lumbar vertebra. The spot was painful on pressure, and had been so ever since the attack of whooping cough three years before. A tap on the sole of either foot made her complain of severe pain in the back. The same result followed pressure on the head. The

patient was unable to stand or walk, but occasionally sat up for a short time, although suffering all the time. There was no muscular rigidity. The limbs and body were quite thin, but, so far as could be detected, she had no loss of motor or sensory power. At times, when the pains were worse, the arms would be flexed involuntarily, and she stated that once the spine was drawn back and a little sideways. The pain in the hips was augmented by pressure. During the application of a plaster bandage she had a sort of fit and fainted, and the application was suspended. She soon recovered consciousness, but refused to allow the completion of the dressing. I diagnosticated the affection as largely hysterical, and a few months later received word that the patient was on her feet and well.

Kemper¹ relates the case of a lady who eventually died of sarcoma of the vertebræ, the specimens having been examined by J. H. C. Simes of Philadelphia and myself. She was supposed at first and for some time to be a case of hysteria with spinal irritation. In the case of a distinguished naval officer, who died of malignant vertebral disease after great suffering a short time since, this same mistake was made during the early stages of the disease: his case was pronounced to be one of neurasthenia, hysteria, etc. before its true nature was finally discovered. The absence of muscular rigidity in the back and extremities is the strongest point against vertebral disease in these cases.

In hysterical hemianæsthesia, ovarian hyperæsthesia, hysterio-epileptic seizures, ischuria, and other well-known hysterical symptoms have usually been observed. The anæsthesia in hysterical cases is most commonly on the left side of the body, but it may happen to be so located in an organic case, so that this point is only one of slight value.

Some older observers, as Briquet, who is quoted and criticised by Charcot, believed that hemianæsthesia from encephalic lesions differed from hysterical hemianæsthesia by the fact that in the former case the skin of the face did not participate in the insensibility, or that when it existed it never occupied the same side as the insensibility of the limbs. Recently-reported cases have disproved the accuracy of this supposed diagnostic mark. In his lectures, delivered ten years ago, Charcot observed that up to that period anæsthesia of general sensibility alone appeared to have been observed as a consecutive on an alteration of the cerebral hemispheres, so that obtunding of the special senses would remain as a distinctive characteristic of hysterical hemianæsthesia. He, however, expected that cases of cerebral organic origin would be reported of complete hemianæsthesia, with derangements of the special senses, such as is presented in hysteria. His anticipations have been fulfilled. In the nervous wards of the Philadelphia Hospital is now a typical case of organic hemianæsthesia in which the special senses are partially involved.

Paralysis and contractures, if present, are apt to be accompanied in cases of organic hemianæsthesia, after time has elapsed, by marked nutritive changes, by wasting of muscle, and even of skin and bone. This is not the case in hysteria.

The subsequent history of these two conditions is different. The hysterical patient will often recover and relapse, or under proper treat-

¹ *Journal of Nervous and Mental Diseases*, vol. xii., No. 1, January, 1885.

ment may entirely recover ; while all the treatment that can be given in a case of organic hemianæsthesia will produce no decided improvement, for there is a lesion in the brain which will remain for ever. Hemianopsia, so far as I know, has not been observed in hysterical hemianæsthesia.

In the monograph of Shaffer, with reference to both true and false knee-joint affections certain conclusions are drawn which I will give somewhat condensed :

Chronic synovitis produces very few if any subjective symptoms ; hysterical imitation presents a long train of both subjective and objective symptoms and signs, the former in excess. Chronic ostitis may be diagnosed if muscular spasm cannot be overcome by persistent effort ; when the spasm does not vary night nor day ; when it is not affected by the ordinary doses of opium or chloral ; when reaction of the muscles to the faradic current is much reduced ; when a local and uniform rise of temperature over the affected articulation is present ; when purely involuntary neural symptoms, such as muscular spasm, pain, and a cry of distress, are present. Hysterical knee-joint is present, according to this author, when the muscular rigidity or contracture is variable, and can be overcome by mildly persistent efforts while the patient's mind is diverted, or which yields to natural sleep, or which wholly disappears under the usual doses of opium or chloral ; when the faradic response is normal ; when rise of temperature is absent or a reduced temperature is present over the joint ; when variable and inconstant, emotional, and semi-voluntary manifestations are present.

To recognize the neuromimesis of hip disease Shaffer gives the following points : The limp is variable and suggests fatigue ; it is much better after rest ; it almost invariably follows the pain. Pain of a hyperæsthetic character is usually the first symptom, and it is found most generally in the immediate region of the joint. "In place of an apprehensive state in response to the tests applied will be found a series of symptoms which are erratic and inconstant. A condition of muscular rigidity often exists, but, unlike a true muscular spasm, it can in most cases be overcome in the manner before stated. A very perceptible degree of atrophy may exist—such, however, as would arise from inertia only. A normal electrical contractility exists in all the muscles of the thigh."

In the neuromimesis of chronic spondylitis or hysterical spine the pain is generally superficial, and is almost always located over or near the spinous processes ; it is sometimes transient, and frequently changes its location from time to time ; a normal degree of mobility of the spinal column under properly directed manipulation is preserved ; the nocturnal cry and apprehensive expression of Pott's disease are wanting.

With reference to the hysterical lateral curvature, Shaffer, quoting Paget, says "ether or chloroform will help. You can straighten the mimic contracture when the muscles cannot act ; you cannot so straighten a real curvature."

In the diagnosis of local hysterical affections one point emphasized by Skey is well worthy of consideration ; and that is that local forms of hysteria are often not seen because they are not looked for. "If," says he, "you will so focus your mental vision and endeavor to distinguish the minute texture of your cases, and look into and not at them, you will

acknowledge the truth of the description, and you will adopt a sound principle of treatment that meets disease face to face with a direct instead of an oblique force." According to Paget, the means for diagnosis in these cases are to be sought—(1) in what may be regarded as the predisposition, the general condition of the nervous system, on which, as in a predisposing constitution, the nervous mimicry of disease is founded; (2) in the events by which, as by exciting causes, the mimicry may be evoked and localized; (3) in the local symptoms in each case.

Local symptoms as a means of diagnosis can sometimes be made use of in general hysteria. A case may present symptoms of either the gravest form of organic nervous disease or the gravest form of hysteria, and be for a time in doubt, when suddenly some special local manifestation appears which cannot be other than hysterical, and which clinches the diagnosis. In a case with profound anæsthesia, with paraplegia and marked contractures, with recurring spasms of frightful character, the sudden appearance of aphonia and apathyria at once cleared all remaining doubt. Herbert Page mentions the case of a man who suffered from marked paraplegia and extreme emotional disturbance after a railway collision, who, nine months after the accident, had an attack of aphonia brought on suddenly by hearing of the death of a friend. He eventually recovered.

To detect hysterical or simulated blindness the methods described by Harlan are those adopted in my own practice. When the blindness is in both eyes, optical tests cannot be applied. Harlan suggests etherization.¹ In a case of deception, conscious or unconscious, he says, "as the effect of the anæsthetic passed off the patient would probably recover the power of vision before his consciousness was sufficiently restored to enable him to resume the deception." Hutchinson cured a case of deaf-dumbness by means of etherization. For simulated monocular blindness Graefe's prism-test may be used: "If a prism held before the eye in which sight is admitted causes double vision, or when its axis is held horizontally a corrective squint, vision with both eyes is rendered certain." It should be borne in mind that the failure to produce double images is not positive proof of monocular blindness, for it is possible that the person may see with either eye separately, but not enjoy binocular vision, as in a case of squint, however slight. Instead of using a prism while the patient is reading with both eyes at an ordinary distance, say of fourteen or sixteen inches, on some pretext slip a glass of high focus in front of the eye said to be sound. If the reading is continued without change, of course the amaurosis is not real. Other tests have been recommended, but these can usually be made available.

The diagnosis of hysterical, simulated, or mimetic deafness is more difficult than that of blindness. When the deafness is bilateral, the difficulty is greater than when unilateral. The method by etherization just referred to might be tried. Politzer in his work on diseases of the ear² makes the following suggestions: Whether the patient can be wakened out of sleep by a moderately loud call seems to be the surest experiment. But, as in total deafness motor reflexes may be elicited by the concussion of loud sounds,

¹ *Loc. cit.*

² *A Textbook of the Diseases of the Ear and Adjacent Organs*, by Adam Politzer, translated and edited by James Patterson Cassells, M. D., M. R. C. S. Eng., Philada., 1883.

care must be taken not to go too near the person concerned and not to call too loudly. The practical objection to this procedure in civil practice would seem to be that we are not often about when our patients are asleep. In unilateral deafness L. Müller's method is to use two tubes, through which words are spoken in both ears at the same time. When unilateral deafness is really present the patient will only repeat what has been spoken in the healthy ear, while when there is simulation he becomes confused, and will repeat the words spoken into the seemingly deaf ear also. To avoid mistakes in using this method, a low voice must be employed.

Mistakes in diagnosis where hysteria is in question are frequently due to that association with it of serious organic disease of the nervous system of which I have already spoken at length under Complications. This is a fact which has not been overlooked by authors and teachers, but one on which sufficient stress has not yet been laid, and one which is not always kept in mind by the practitioner. Bramwell says: "Cases are every now and again met with in which serious organic disease (myelitis and poliomyelitis, anterior, acute, for example) is said to be hysterical. Mistakes of this description are often due to the fact that serious organic disease is frequently associated with the general symptoms and signs of hysteria; it is, in fact, essential to remember that all cases of paraplegia occurring in hysterical patients are not necessarily functional—*i. e.* hysterical; the presence of hysteria or a history of hysterical fits is only corroborative evidence, and the (positive) diagnosis of hysterical paraplegia should never be given unless the observer has, after the most careful examination, failed to detect the signs and symptoms of organic disease."

PROGNOSIS.—Hysteria may terminate (1) in permanent recovery; (2) in temporary recovery, with a tendency to relapse or to the establishment of hysterical symptoms of a different character; (3) in some other affection, as insanity, phthisis, or possibly sclerosis; (4) in death, but the death in such cases is usually not the direct result of hysteria, but of some accident. Death from intercurrent disorders may take place in hysteria. It is altogether doubtful, however, whether the affection which has been described as acute fatal hysteria should be placed in the hysterical category. In the cases reported the symptom-picture would in almost every instance seem to indicate the probability of the hysteria having been simply a complication of other disorders, such as epilepsy, eclampsia, and acute mania.

As a rule, hysterical patients will not starve themselves. They may refuse to take food in the presence of others, or may say they will not eat at all; but they will in some cases at the same time get food on the sly or hire their nurses or attendants to procure it for them. In treating such cases a little watchfulness will soon enable the physician to determine what is best to be done. By discovering them in the act of taking food future deception can sometimes be prevented. Hysterical patients do sometimes, however, persistently refuse food. These cases may starve to death if let alone; and it is important that the physician should promptly resort to some form of forcible feeding before the nutrition of the patient has reached too low an ebb. I have seen at least two cases of hysteria or hysterical insanity in which patients were practically allowed to starve themselves to death, but an occurrence of

this kind is very rare. Feeding by means of a stomach-tube, or, what is still better, by a nasal tube, as is now so frequently practised among the insane, should be employed. Nourishment should be administered systematically in any way possible until the patient is willing to take food in the ordinary way. In purposive cases some methods of forcible feeding may prove of decided advantage. Its unpleasantness will sometimes cause swallowing power to be regained.

Wunderlich¹ has recorded the case of a servant-girl, aged nineteen, who, after a succession of epileptiform fits, fell into a collapse and died in two days. Other cases have been recorded by Meyer. Fagge also speaks of the more chronic forms of hysteria proving fatal by marasmus. He refers to two cases reported by Wilks, both of which were diagnosed as hysterical, and both of which died. Sir William Gull describes a complaint which he terms *anorexia nervosa vel hysterica*. It is attended with extreme wasting; pulse, respiration, and temperature are low. The patients were usually between the ages of sixteen and twenty-three; some died; others recovered under full feeding and great care. In many of the reported fatal cases careful inquiry must be made as to this question of hysteria being simply a complication.

Are not hysterical attacks sometimes fatal? With reference to one of my cases this view was urged by the physician in attendance. Gowers² on this point says: "As a rule to which exceptions are infinitely rare, hysterical attacks, however severe and alarming in aspect, are devoid of danger. The attacks of laryngeal spasm present the greatest apparent risk to life." He refers to the paroxysms of dyspnoea presented by a hemiplegic girl as really alarming in appearance, even to those familiar with them. He refers also to a case of Raynaud's³ in which the laryngeal and pharyngeal spasm coexisted with trismus, and the patient died in a terrible paroxysm of dyspnoea. The patient presented various other hysterical manifestations, and a precisely similar attack had occurred previously and passed away, but she had in the interval become addicted to the hypodermic injection of morphia, and Raynaud suggested that it might have been the effect of this on the nerve-centres that caused the fatal termination. Such cases have been described in France as the hydrophobic form of hysteria.

Patients may die in hysterical as in epileptic attacks from causes not directly connected with the disease. One of these sources of danger mentioned by Gowers is the tendency to fall on the face sometimes met with in the post-epileptic state. He records an example of death from this cause. He also details a case of running hysteria or hysterio-epilepsy, in which, after a series of fits lasting about four hours, the child died, possibly from some intercurrent accident.

TREATMENT.—Grasset,⁴ speaking of the treatment of hysteria, says that means of treating the paroxysm, of removing the anæsthesia, of combating single symptoms, are perhaps to be found in abundance, but the groundwork of the disease, the neurosis or morbid state, is not attacked. Here he indicates a new and fruitful path. In his own sum-

ming up, however, he can only say that the hysterical diathesis offers fundamental grounds for the exhibition of arsenic, silver, chloride of gold, and mineral waters!

No doubt can exist that the prophylactic and hygienic treatment of hysteria is of paramount importance. To education—using the term education in a broad sense—before and above all, the most important place must be given. It is sometimes better to remove children from their home surroundings. Hysterical mothers develop hysterical children through association and imitation. I can scarcely, however, agree with Dujardin-Beaumetz that it is always a good plan to place a girl in a boarding-school far from the city. It depends on the school. A well-regulated institution may be a great blessing in this direction; one badly-managed may become a hotbed of hysteria.

Recently I made some investigations into the working of the public-school system of Philadelphia, particularly with reference to the question of overwork and sanitation.¹ I had special opportunities during the investigations to study the influences of different methods of education, owing to the fact that the public-school system of Philadelphia is just now in a transition period. This system is in a state of hopeful confusion—hopeful, because I believe that out of its present condition will come eventually a great boon to Philadelphia. At one end of the system, in the primary and the secondary schools, a graded method of instruction has been introduced. The grammar and the high schools are working on an ungraded or differently graded method. I found still prevailing, particularly in certain of the grammar schools for girls, although not to the same extent as a few years since, methods of cramming and stuffing calculated above all to produce hysteria and allied disorders in those predisposed to them.

Education should be so arranged as to develop the brain by a natural process—not from within outward; not from the centre to the periphery; not from above downward; but as the nervous system itself develops in its evolution from a lower to a higher order of animals, from the simple to the more complex and more elaborate. Any system of education is wrong, and is calculated to weaken and worry an impressionable nervous system, which attempts to overturn or change this order of the progress of a true development of the brain. To develop the nervous system as it should be developed—slowly, naturally, and evenly—it must also be fed, rested, and properly exercised.

In those primary schools in which the graded method was best carried out this process of helping natural development was pursued, and the result was seen in contented faces, healthy bodies, and cheerful workers. In future the result will be found in less chorea, hysteria, and insanity.

To prevent the development of hysteria, parents and physicians should direct every effort. The family physician who discovers a child to be neurotic, and who from his knowledge of parents, ancestors, and collateral relatives knows that a predisposition to hysteria or some other neurosis is likely to be present, should exercise all the moral influence which he possesses to have a healthy, robust training provided. It is not within the

¹ The results of these investigations were given in a lecture which was delivered in the Girls' Normal School of Philadelphia before the Teachers' Institute of Philadelphia, Dec. 11, 1885.

scope of an article of this kind to describe in great detail in what such education should consist. Reynolds is correct when he says that "self-control should be developed, the bodily health should be most carefully regarded, and some motive or purpose should be supplied which may give force, persistence, unity, and success to the endeavors of the patient." In children who have a tendency to the development of hysteria the inclinations should not always or altogether be regarded in choosing a method or pursuing a plan of education. It is not always to what such a child takes that its mind should be constantly directed; but, on the contrary, it is often well to educate it away from its inclination. "The worst thing that can be done is that which makes the patient know and feel that she is thought to be peculiar. Sometimes such treatment is gratifying to her, and she likes it—it is easy and it seems kind to give it—but it is radically wrong."

In providing for the bodily health of hysterical children it should be seen that exercise should be taken regularly and in the open air, but over-fatigue should be avoided; that ample and pleasant recreation should be provided; that study should be systematic and disciplinary, but at the same time varied and interesting, and subservient to some useful purpose; that the various functions of secretion, excretion, menstruation should be regulated.

The importance of sufficient sleep to children who are predisposed to hysteria or any other form of nervous or mental disorder can scarcely be over-estimated. The following, according to J. Crichton Browne,¹ is the average duration of sleep required at different ages: 4 years of age, 12 hours; 7 years of age, 11 hours; 9 years of age, 10½ hours; 14 years of age, 10 hours; 17 years of age, 9½ hours; 21 years of age, 9 hours; 28 years of age, 8 hours. To carefully provide that children shall obtain this amount of sleep will do much to strengthen the nervous system and subdue or eradicate hysterical tendencies. Gymnastics, horseback riding, walking, swimming, and similar exercises all have their advantages in preventing hysterical tendencies.

Herz² has some instructive and useful recommendations with reference to the treatment of hysteria in children. It is first and most important to rehabilitate the weakened organism, and especially the central nervous system, by various dietetic, hygienic, and medicinal measures. It is important next to tranquillize physical and mental excitement. This can sometimes be done by disregard of the affection, by neglect, or by removal or threatened removal of the child from its surroundings. Such treatment should of course be employed with great discretion. Anæmia and chlorosis, often present in the youthful victims of hysteria, should be thoroughly treated. Care should be taken to learn whether children of either sex practise masturbation, which, Jacobi and others insist, frequently plays an important part in the production of hysteria. Proper measures should be taken to prevent this practice. The genital organs should receive examination and treatment if this is deemed at all necessary. On the other hand, care should be taken not to direct the attention of children unnecessarily to those organs when they are entirely innocent

¹ *Education and the Nervous System*, reprinted from *The Book of Health* by permission of Messrs. Cassell & Co., Limited.

² *Wien. Med. Wochen.*, No. 46, Nov. 14, 1885.

of such habits. Painting the vagina twice daily with a 10 per cent. solution of hydrochlorate cocaine has been found useful in subduing the hyper-irritation of the sexual organs in girls accustomed to practise masturbation. Herz, with Henoeh, prefers the hydrate of chloral to all other medicines, although he regards morphine as almost equally valuable, in the treatment of hysteria in children. Personally, I prefer the bromides to either morphia or chloral. Small doses of iron and arsenic continued systematically for a long period will be found useful. Politzer of Vienna regards the hydrobromate and bihydrobromate of iron as two valuable preparations in the hysteria of children, and exhibits them in doses of four to seven grains three to four times daily.

Hysteria once developed, it is the moral treatment which often really cures. The basis of this method of cure is to rouse the will. It is essential to establish faith in the mind of the patient. She must be made to feel not only that she can be helped, but that she will be. Every legitimate means also should be taken to impress the patient with the idea that her case is fully understood. If malingering or partial malingering enters into the problem, the patient will then feel that she has been detected, and will conclude that she had better get out of her dilemma as gracefully as possible. Where simulation does not enter faith is an important nerve-stimulant and tonic; it unchains the will.

Many physicians have extraordinary ideas about hysteria, and because of these adopt remarkable and sometimes outrageous methods of treatment. They find a woman with hysterical symptoms, and forthwith conclude she is nothing but a fraud. They are much inclined to assert their opinions, not infrequently to the patient herself, and, if not directly to her, in her hearing to other patients or to friends, relatives, nurses, or physicians. They threaten, denounce, and punish—the latter especially in hospitals. In general practice their course is modified usually by the wholesome restraint which the financial and other extra-hospital relations of patient and physician enforce.

Although hysterical patients often do simulate and are guilty of fraud, it should never be forgotten that some hysterical manifestations may be for the time being beyond the control of patients. Even for some of the frauds which are practised the individuals are scarcely responsible, because of the weakness of their moral nature and their lack of will-power. Moral treatment in the form of reckless harshness becomes immoral treatment. The liability to mistake in diagnosis, and the frequent association of organic disease with hysterical symptoms, should make the physician careful and conservative. It is also of the highest importance often that the doctor should not show his hand. The fact that an occasional cure, which is usually temporary, is effected by denunciation, and even cruelty, is not a good argument against the stand taken here.

Harsh measures should only be adopted after due consideration and by a well-digested method. A good plan sometimes is, after carefully examining the patient, to place her on some simple, medicinal, and perhaps electrical treatment, taking care quietly to prophesy a speedy cure. If this does not work, in a few days other severe or more positive measures may be used, perhaps blistering or strong electrical currents. Later, but in rare cases only, after giving the patient a chance to arouse

herself by letting her know what she may expect, painful electrical currents, the hot iron, the cold bath, or similar measures may be used. Such treatment, however, should never be used as a punishment.

The method of cure by neglect can sometimes be resorted to with advantage. The ever-practical Wilks mentions the case of a school-teacher with hemianalgesia, hemianæsthesia, and an array of other hysterical symptoms who had gone through all manner of treatment, and at the end of seven months was no better. The doctor simply left her alone. He ordered her no drugs, and regularly passed by her bed. In three weeks he found her sitting up. She talked a little and had some feeling in her right side. She was now encouraged, and made rapid progress to recovery. Neglect had aroused her dormant powers. It must be said that a treatment of this kind can be carried out with far more prospects of success in a general hospital than in a private institution or at the home of a patient. It is a method of treatment which may fail or succeed according to the tact and intelligence of the physician.

I cannot overlook here the consideration of the subject of the so-called faith cure and mind cure. One difference between the faith cure as claimed and practised by its advocates, and by those who uphold it from a scientific standpoint, is simply that the latter do not refer the results obtained to any supernatural or spiritual agency. I would not advise the establishment of prayer-meetings for the relief of hysteria, but would suggest that the power of faith be exercised to its fullest extent in a legitimate way.

A young lady is sick, and for two years is seen by all the leading doctors in London; a clergyman is asked in and prays over her, and she gets up and walks. The doctors all join in and say the case was one of hysteria—that there was nothing the matter with her. Then, says Wilks, “Why was the girl subjected to local treatment and doses of physic for years? Why did not the doctors do what the parson did?”

Tuke¹ devotes a chapter to psychotherapeutics, which every physician who is called upon to treat hysteria should read. He attempts to reduce the therapeutic use of mental influence to a practical, working basis. I will formulate from Tuke and my own experience certain propositions as to the employment of psychological measures: (1) It is often important and always justifiable to inspire confidence and hope in hysterical patients by promising cures when it is possible to achieve cures. (2) A physician may sometimes properly avail himself of his influence over the emotions of the patient in the treatment of hysterical patients, but always with great caution and discretion. (3) Every effort should be made to excite hysterical patients to exert the will. (4) In some hysterical cases it is advisable to systematically direct the attention to a particular region of the body, arousing at the same time the expectation of a certain result. (5) Combined mental and physical procedures may sometimes be employed. (6) Hypnotism may be used in a very few cases.

The importance of employing mental impression is thoroughly exemplified, if nothing else is accomplished, by a study of such a craze as the so-called mind cure. Not a few people of supposed sense and cultivation have pinned their faith to this latest Boston hobby. A glance at the published writings of the apostles of the mind cure will show at once to the

¹ *Influence of the Mind upon the Body.*

critical mind that all in it of value is dependent upon the effects of mental impression upon certain peculiar natures, some of them being of a kind which afford us not a few of our cases of hysteria. W. F. Evans has published several works upon the subject. From one of these¹ I have sought, but not altogether successfully, to obtain some ideas as to the basis of the mind-cure treatment. It is claimed that the object is to construct a theoretical and practical system of phrenopathy, or mental cure, on the basis of the idealistic philosophy of Berkeley, Fichte, Schelling, and Hegel. The fundamental doctrine of those who believe in the mental cure is, that to think and to exist are one and the same, and that every disease is a translation into a bodily expression of a fixed idea of mind. If by any therapeutic device the morbid idea can be removed, the cure of the malady is assured. When the patient is passive, and consequently impressible, he is made to fix his thoughts with expectant attention upon the effect to be produced. The physician thinks to the same effect, wills it, and believes and imagines that it is being done; the mental action to the patient, sympathizing with that of the physician, is precipitated upon the body, and becomes a silent, transforming, sanitive energy. It must be, says Evans, "a malady more than ordinarily obstinate that is neither relieved nor cured by it."

Hysteria cannot be cured by drugs alone, and yet a practitioner of medicine would find it extremely difficult to manage some cases without using drugs. Drugs themselves, used properly, may have a moral or mental as well as a physical influence. Among those which have been most used from before the days of Sydenham to the present time, chiefly for their supposed or real antispasmodic virtues, are galbanum, asafœtida, valerian, castor and musk, opium, and hyoscyamus. The value of asafœtida, valerian, castor, and musk is chiefly of a temporary character. If these drugs are used at all, they should be used in full doses frequently repeated. Sumbul, a drug of the same class comparatively little used, is with me a favorite. It can be used in the form of tincture or fluid extract, from twenty minims to half a drachm of the latter or one to two drachms of the former. It certainly has in many cases a remarkably calmative effect.

Opium and its preparations, so strongly recommended by some, and especially the Germans, should not be used except in rare cases. Occasionally in a case with sleeplessness or great excitement it may be absolutely indispensable to resort to it in combination with some other hypnotic or sedative. The danger, however, in other cases of forming the opium habit should not be overlooked. According to Dujardin-Beaumont, it is mainly useful in the asthenic forms of hysteria.

Of all drugs, the metallic tonics are to be preferred in the continuous treatment of hysteria. Iron, although not called for in a large percentage of cases, will sometimes prove of great service in the weak and anæmic hysterics. Chalybeates are first among the drugs mentioned by Sydenham. Steel was his favorite. The subcarbonate or reduced iron, or the tincture of the chloride, is to be preferred to the more fanciful and elegant preparations with which the drug-market is now flooded. Dialyzed iron and the mallate of iron, however, are known to be reliable preparations, and can be resorted to with advantage. They should be given in large doses. Zinc salts, particularly the oxide, phosphide, and valerian-

¹ *The Divine Law of Cure.*

ate; the nitrate or oxide of silver, the ammonio-sulphate of copper, ferri-ferrocyanide or Prussian blue,—all have a certain amount of real value in giving tone to the nervous system in hysterical cases.

To Niemeyer we owe the use of chloride of sodium and gold in the treatment of hysteria. He refers to the fact that Martini of Biberach regarded this article as an efficient remedy against the various diseases of the womb and ovaries. He believed that the improvement effected upon Martini's patient was probably due to the fact that this, like other metallic remedies, was an active nervine. He prescribed the chloride of gold and sodium in the form of a pill in the dose of one-eighth of a grain. Of these pills he at first ordered one to be taken an hour after dinner, and another an hour after supper. Later, he ordered two to be taken at these hours, and gradually the dose was increased up to eight pills daily. I frequently use this salt after the method of Niemeyer.

The treatment of hysteria which Mitchell has done so much to make popular, that by seclusion, rest, massage, and electricity, is of value in a large number of cases of grave hysteria; but the proper selection of cases for this treatment is all important. Playfair¹ says correctly that if this method of treatment is indiscriminately employed, failure and disappointment are certain to result. The most satisfactory results are to be had in the thoroughly broken-down and bed-ridden cases. "The worse the case is," he says, "the more easy and certain is the cure; and the only disappointments I have had have been in dubious, half-and-half cases."

Mitchell² gives a succinct, practical description of the process of massage: "An hour," he says, "is chosen midway between two meals, and, the patient lying in bed, the manipulator starts at the feet, and gently but firmly pinches up the skin, rolling it lightly between his fingers, and going carefully over the whole foot; then the toes are bent and moved about in every direction; and next, with the thumbs and fingers, the little muscles of the foot are kneaded and pinched more largely, and the interosseous groups worked at with the finger-tips between the bones. At last the whole tissues of the foot are seized with both hands and somewhat firmly rolled about. Next, the ankles are dealt with in the same fashion, all the crevices between the articulating bones being sought out and kneaded, while the joint is put in every possible position. The leg is next treated—first by surface pinching and then by deeper grasping of the areolar tissue, and last by industrious and deeper pinching of the large muscular masses, which for this purpose are put in a position of the utmost relaxation. The grasp of the muscles is momentary, and for the large muscles of the calf and thigh both hands act, the one contracting as the other loosens its grip. In treating the firm muscles in front of the leg the fingers are made to roll the muscles under the cushions of the finger-tips. At brief intervals the manipulator seizes the limb in both hands and lightly runs the grasp upward, so as to favor the flow of venous blood-currents, and then returns to the kneading of the muscles. The same process is carried on in every part of the body, and especial care is given to the muscles of the loins and spine, while usually the face

¹ *The Systematic Treatment of Nerve-Prostration and Hysteria*, by W. S. Playfair, M. D., F. R. C. P., 1883.

² "Fat and Blood," etc.

is not touched. The belly is first treated by pinching the skin, then by deeply grasping and rolling the muscular walls in the hands, and at last the whole belly is kneaded with the heel of the hand in a succession of rapid, deep movements, passing around in the direction of the colon."

Massage should often be combined with the Swedish movement cure. In the movement cure one object is to call out the suppressed will of the patient. This is very applicable to cases of hysteria. The cure of cases of this kind is often delayed by using massage alone, which is absolutely passive. These movements are sometimes spoken of as active and passive, or as single and duplicated. Active movements are those more or less under the control of the individual making or taking part in them, and they are performed under the advice or direction, and sometimes with the assistance, of another. They proceed from within; they are willed. Passive movements come from without; they are performed on the patient and independently of her will. She is subjected to pushings and pullings, to flexions and extensions, to swingings and rotations, which she can neither help nor hinder. The same movement may be active or passive according to circumstances. A person's biceps may be exercised through the will, against the will, or with reference to the will.

A single movement is one in which only a single individual is engaged; speaking medically, single movements are those executed by the patient under the direction of the physician or attendant; they are, of course, active. Duplicated active movements require more than one for their performance. In these the element of resistance plays an important part. The operator with carefully-considered exertion performs a movement which the patient is enjoined to resist, or the latter undertakes a certain motion or series of motions which the former, with measured force, resists. Still, tact and experience are here of great value, in order that both direct effort and resistance should be carefully regulated and properly modified to suit all the requirements of the case. By changing the position of the patient or the manner of operating on her from time to time any muscles or groups of muscles may be brought into play. It is wonderful with what ease even some of the smallest muscles can be exercised by an expert manipulator.

The duplicated active movements are those which should be most frequently performed or attempted in connection with massage in hysterical patients. The very substance of this treatment is to call out that which is wanting in hysteria—will-power. It is a coaxing, insinuating treatment, and one which will enable the operator to gain control of the patient in spite of herself. As the patient exerts her power the operator should yield and allow the part to be moved.

Much of the value of massage and Swedish movements, in hysteria as in other disorders, is self-evident. Acceleration of circulation, increase of temperature, direct and reflex stimulation of nervous and muscular action, the promotion of absorption by pressure,—these and other results are readily understood. "The mode in which these gymnastic proceedings exert an influence," says Erb,¹ "consists, no doubt, in occasioning frequently-repeated voluntary excitations of the nerves and muscles, so that the act of conduction to the muscles is gradually rendered

¹ Ziemssen's *Cyclopædia*.

more facile, and ultimately the nutrition of the nerves and muscles is augmented."

The objects to be attained by the use of electricity are nearly the same as from massage and duplicated active movements: in the first place, to improve the circulation and the condition of the muscles; and in the second place, to make the patient use the muscles. The faradic battery should be employed in these cases, and the patient should be in a relaxed condition, preferably in bed. A method of electrical treatment introduced some years ago by Beard and Rockwell is known as general faradization. This is sometimes used in the office of the physician. In this method the patient is placed in a chair with his feet on a large plate covered with chamois-skin; the operator then takes hold of the patient's hand and the other electrode is passed over the muscles of the neck, back, trunk, and extremities.

When the patient is in bed, as in the regular rest treatment, this method has to be modified, and then the best treatment is by direct muscular faradization. Two sponge electrodes are employed. The sponges are moistened, so that the current may pass through the skin and reach the muscles. Both electrodes are taken in one hand, the handle of one, pointing backward, being between the first and second fingers, while the handle of the other is between the third and fourth fingers. In this way the distance between the points of application can be readily altered. The current is then applied to the muscles everywhere, beginning with those of the feet. Muscles should be relaxed before passing the current through them. The whole body can be gone over in this way in the course of half an hour.

The hydropathic treatment of hysteria is one that has much in it to be commended. Jolly approves the systematic external application of cold water; Chambers advocates the daily morning use of shower-baths, holding that the bracing up of the mind to the shock of a cold shower-bath is a capital exercise for the weak will-power of the hysterical individual, and some admirable results have been reported by Charcot in inveterate neurasthenics and hysterics. Hydrotherapeutic treatment, continued perseveringly for a long time, says Rosenthal, "diminishes the extreme impressionability of hysterical patients, strengthens them, and increases their power of resistance to irritating influences, stimulates the organic functions, combats the anæmia, calms the abnormal irritability of the peripheral nervous system, and by diminishing the morbid increase of reflex power relieves the violence of the spasmodic symptoms. Even chronic forms which are combined with severe paroxysms of convulsions are susceptible of recovery under this plan of treatment."

The hydrotherapeutic treatment may be contrasted with the treatment by seclusion, rest, massage, and electricity. Undoubtedly, one class of hysterical patients is greatly benefited by the latter method systematically carried out; these have already been described. In other cases, however, this method of treatment is useless; in some of them it has a tendency to prolong or aggravate the hysterical disorder, while in the same cases a well-managed hydrotherapeutic treatment will answer admirably. This is applicable in hysterical patients who eat and drink well, who, as a rule, preserve a good appearance, but whose mind and muscles are equally flabby and out of tone, and need to be stirred up both physically and mentally.

Dujardin-Beaumetz recommends prolonged warm baths of from one to two hours' duration, and believes that the therapeutic virtues of these baths are augmented by infusions of valerian.

In order to obtain satisfactory results from hydrotherapy, as well as from massage, electricity, etc., it is best to remove patients from their family surroundings. Good sanitariums near our large American cities where hydrotherapy and other special methods of treatment can be carried out are sadly needed. Hydrotherapeutic treatment is much more efficacious when conducted at a well-regulated institution, for several reasons. Measures troublesome in themselves are here carried out as a matter of daily routine. Numerous patients permit of the employment of competent attendants. The change is often of great benefit. The close personal supervision which hysterical patients are likely to have in a hydrotherapeutic establishment is also to be taken into consideration. Better modes of living, proper forms of exercise, regulated diet, etc. also enter; but still, a fair share of the good which results can be attributed to the water treatment.

While, however, it is better to remove hysterical patients, for hydrotherapeutic as well as for other treatment, from their family surroundings, and to place them in some well-regulated establishment, it is not by any means impossible to carry out such treatment in private practice, particularly in a house supplied with a bath-room. Many of our hydrotherapeutic institutions are in the hands of charlatans or of individuals who are not practically well fitted for their work. Not infrequently, however, good results are obtained even under these circumstances. Much more can be done in this direction with modest buildings and appliances than is generally supposed. It is not necessary to have numerous apartments: three or four rooms in a well-appointed house, if the arrangements for carrying out the hydrotherapeutic treatment are of a proper kind, will suffice for a large amount of good work. In almost any house provided with bath-rooms with hot and cold water some useful hydrotherapy may be attempted. The spinal douche or pour can be used by placing the patient in a sitz- or ordinary hip-bath and pouring the water from a spout or hose held at a certain height, the distance being regulated according to the patient's condition. Again, the patient sitting in a tub, water can be poured upon her, beginning at first with a high temperature and gradually lowering it. The shower-bath may also be used. An extemporaneous shower-bath can be provided by an ordinary watering-pot. Whole, three-quarters, or half baths at different temperatures can be given. One method of carrying out the wet pack is very simple. A comforter is spread upon the bed; next to this is placed a woollen blanket, and over the blanket a wet linen sheet, upon which the patient rests, with the head on a low pillow. The wet sheet, blanket, and comforter are then wrapped closely about the patient, bottles of hot water being placed at the feet. The cold drip-sheet method is another easily used. It consists in placing about the patient, while sitting up or standing, a sheet wet with cold water, and then vigorously rubbing her through the sheet.

Baths to the head may be used in some cases; cool head-baths are most frequently applied. One method of using these baths is to have the patient lie in such a position that the head projects a little beyond the

edge of the bed and over a basin or receptacle of some kind. Water of a suitable temperature is then poured gently or squeezed out of a sponge over the head. For some forms of insomnia or some of the disorders of sleep in hysteria this treatment is a valuable auxiliary to other measures.

For the hysterical spine cold compresses may be used along the spine. On the other hand, hot fomentations may be found of benefit in some cases. Where hydrotherapeutic measures are employed attention should be paid to the condition of the circulation, particularly in the extremities. If the feet or hands are cold, hot applications or frictions should be used.

For certain of the vaso-motor disorders of hysteria, such as cold or hot feet, flushings, etc., local hydrotherapeusis will be of service. In hysterical contractures local stimulation by the douche method or by the steam bath may be tried. For the excitable rectum cold enemata in small quantities, so as not to be expelled, will be found to be very efficacious. For spasmodic attacks, whether purposive or involuntary, the use of the wet pack or the plunge-bath will sometimes be found of good service. In neuralgias and other painful local disorders of hysteria, frictions, fomentations, Turkish or Russian baths, and the wet pack are often very beneficial.

When hysteria is complicated, as it very often is, with disorders of the liver and stomach, hydrotherapeutic measures will be of added efficacy. When it is associated with genito-urinary disorders, even though the latter are not regarded as the cause of the former, special beneficial effects, both local and general, can be obtained from hydrotherapeutic measures. Locally, sitz-baths, hip-baths, douche-baths, hot and cold injections, and foot-baths may act as revulsives, astringents, or local tonics, while at the same time they are measures which tend to strengthen the system as a whole.

Sea-bathing is often of the greatest value, although it is sometimes difficult to induce hysterical patients, who are willing enough to go to the seashore, to resort to surf-bathing. Few measures are better calculated to bring up the tone of the nervous system of an hysterical or neurasthenic patient than well-directed sea-bathing. Where sea-bathing cannot be employed sea-water may be used indoors. Sea-water establishments, where baths at various temperatures may be had, are now to be found at all the best seaside resorts. In a few cases the internal use of large quantities of either hot or cold water, or of the ferruginous mineral waters, may be associated with the external treatment.

The climatic treatment of hysteria has received little or no attention; undoubtedly, much could be said in this connection. In a great country like ours a climate suited to the requirements of almost every form of disease can be had. The climate of those regions, either of the seaboard or inland, particularly well suited to cases of lung trouble, will often be useless, and sometimes harmful, to neurotic patients. For a certain class of hysterical patients a sojourn at the seashore, if not too protracted, will prove of great value. On the whole, for most hysterical patients of the neurasthenic type the best plan is to go first to the seashore for a few weeks, and then resort to an inland hilly or mountainous country, but not at too great an elevation. I have known the climate of some of the high altitudes of Colorado to be of positive injury by depressing the nervous system. Resorts like Capon Springs in West Virginia, out of

the reach of steam and worry, with prevailing south-west winds, are desirable places.

The treatment of hysteria by the method of metallotherapy is worthy of some consideration. It is a method by no means new. It was known and practised by the ancients with rings and amulets. Popularized at the beginning of the present century by certain travelling charlatans, it was later, for a time, wholly ignored. In recent years it has been received with considerable attention. One Burq for many years practised metallotherapy in Paris disregarded or scouted by the profession, but claiming many remarkable cures. Finally, Charcot was induced to give him an opportunity of demonstrating the truth or falsity of his claims at Salpêtrière.¹ Cases of grave hysteria were submitted to the treatment, and in certain instances with striking results.

After having determined by a series of experiments the particular metal to which the patient is sensitive, bits of metal may be applied to the surface of the body in various places; this constitutes external metallotherapy. Or the metal, in the form of powder (as reduced iron) or an oxide or some other salt, may be administered; this is internal metallotherapy. That certain definite effects may be produced by the application of metals to the surface of the body is unquestionable. Some of the results which have followed their employment are the removal of anæsthesia and analgesia, relief of hysterical paralysis, improvement in the circulation, removal of achromatopsia, relief of contracture.

Many investigations in Germany, England, France, and this country have demonstrated that the same or similar effects can be produced by the application of other non-metallic substances, such as discs of wood, minerals, mustard plasters, etc. Hammond, among others, has shown this. How the results are obtained is still a matter of dispute. On the one hand, it is claimed, principally by the French observers, that the cures are due to the metals themselves, either by virtue of some intrinsic power or through some electrical currents generated by their application. On the other hand, it is asserted, particularly by the English observers, that the phenomena are best explained on the doctrine of the influence of the mind on the body; in other words, by the principle of expectant attention. Some at least of the effects are to be explained on the latter hypothesis, but it is likely that the monotonous impressions made upon the peripheral sense-organs by different substances applied locally may act reflexly on the brain.

Seguin² reports a case of convulsion and hemianæsthesia in an adult male cured by metallotherapy; the metal used was gold. Two ordinary twenty-dollar gold pieces were placed in the patient's hands, and afterward on his forearm, cheek, and tongue. Nothing else was suggested or done to him; sensibility returned, and the staggering and other symptoms disappeared. The patient left the hospital claiming to be perfectly well. The same author reports several other successful cases of metallotherapy, all of them reactions to gold. One was a girl sixteen years old with analgesia.

Not a few cases are now on record of the cure of hysterical contracture and other forms of local hysterical disorders by the application of a magnet. Charcot and Vigouroux cured one case of hysterical contracture

¹ *Lancet*, Jan. 19, 1878.

² *Arch. of Medicine*, New York, 1882.

of the left arm by repeated applications of the magnet to the right or healthy arm. Debove by prolonged application of magnets relieved hemianæsthesia and hemiplegias—not only the hysterical varieties, but also, it is said, when dependent upon such conditions as alcoholism, plumbism, and even cerebral lesions. Maggiorani of Rome studied the physiological action of the magnet and laid down the first rules for its therapeutic use. In the case of powerful magnets we have more room for believing that an actual, tangible force is at work in producing the results than in the case of simple metals.

The question has been sometimes asked whether hypnotism can be used with success in the treatment of hysteria. Richer reports a few cures of hysteria through this agency. Braid has put on record between sixty and seventy cases which he claims to have cured by the same means. This list undoubtedly includes some hysterical cases—of paralysis, anæsthesia, aphonia, blindness and deafness, spinal irritation, etc. Both on theoretical grounds and from experience, however, I believe that the practice of hypnotization may be productive of harm in some cases of hysteria, and should be resorted to only in rare cases of mental or motor excitement.

By some, special measures during the hysterical fit are regarded as unnecessary. Jolly, for instance, says that we must merely take care that the patients do not sustain injury in consequence of their convulsive movements, and that respiration is not impeded by their clothing. Rothrock¹ reports several cases of hysterical paroxysms relieved by the application of either snow or ice to the neck. The applications were made by stroking up and down either side of the neck along the line of the sterno-cleido-mastoid muscles. He believed that the most probable explanation of the results obtained was the shock received from the cold substance, but that supplemental to this there may have been supplied through the pneumogastric nerve a *besoin de respirer*. This measure and the use of the cold spinal douche are both to be recommended.

Emetics are sometimes valuable. Miles² reports several cases of severe hysterical seizure in which tobacco was promptly efficient in controlling the affection. He used the *vinum tabaci* in doses of one drachm every half hour or hour until the system was relaxed and nausea induced, the effects usually being produced after taking three or four doses. Fifteen grains of sulphate of zinc may be used in adult cases. James Allen for a case of hysterical coma successfully used a hypodermic injection of one-tenth of a grain of apomorphia. Recently, at the Philadelphia Hospital this remedy has been successfully employed in two cases, one of hysterical coma and the other of hysterical mania. Inhalations of nitrite of amyl are often of surprising efficiency. This and other measures referred to under HYSTERO-EPILEPSY are also applicable in the treatment of any form of hysterical spasm.

For hysterical convulsions occurring during pregnancy an enema of asafetida, camphor, the yolk of an egg, and water, such as has been recommended by Braun of Vienna, will often be found promptly efficacious.

Fagge³ mentions a procedure which he had often seen adopted by Stocker—namely, pressure upon the arteries and other structures on each side of the neck.

² *Clinical Med. Reporter*, 1871, iv. 25 27.

³ *British Medical Journal*, March 27, 1880.

For hysterical paralysis faradism and galvanism hold the chief place. Metallic-brush electricity should be used in the treatment of anæsthesia.

Whenever, in local hysteria, particularly of the paralytic, ataxic, or spasmodic form, it is possible to coax or compel an organ or part to perform its usual function long unperformed or improperly performed, treatment should be largely directed to this end. Thus, as Mitchell has shown, in some cases of aphonia, especially in those in which loss of voice is due to the disassociation of the various organs needed in phonation, by teaching the patient to speak with a very full chest an involuntary success in driving air through the larynx may sometimes be secured. Once compel a patient by firm but gentle means to swallow, and œsophageal paralysis begins to vanish.

Mitchell makes some interesting remarks upon the treatment of the peculiar disorders of sleep, which he describes and to which I have referred. When the symptoms are directly traceable to tobacco, he believes that strychnia and alcohol are the most available remedies, but gives a warning against the too liberal use of the latter. A treatment which was suggested to him by a clever woman who suffered from these peculiar attacks consists in keeping in mind the need of breaking the attack by motion and by an effort of the will. As soon as the attack threatens the patient should resolutely turn over, sit up, or jump out of bed, and move about, or in some such way overcome the impending disorder. Drugs are of little direct use. Small doses of chloral or morphia used until the habit is broken may answer, but general improvement in health, proper exercise, good food, and natural sleep are much more efficient.

Fagge says that he has seen more benefit in hysterical contracture from straightening the affected joints under chloroform, and placing the limb upon a splint, than from any other plan of treatment. Hammond¹ (at a meeting of the New York Neurological Society, Nov. 6, 1876) reports a case of supposed hysterical contracture in the form of wry neck, in which he divided one sterno-cleido-mastoid muscle; immediately the corresponding muscle of the other side became affected; he cut this; then contraction of other muscles took place, which he kept on cutting. The case was given up, and got well spontaneously about two years later. Huchard² entirely relieved an hysterical contracture of the forearm by the application of an elastic bandage.

A lady with violent hysterical cough was chloroformed by Risel of Messeberg³ for fourteen days at every access of the cough, and another for eight days. In both the symptoms were conquered. Nitrite of amyl is useful in similar cases.

Graily Hewitt⁴ reports a case of hysterical vomiting of ten months' duration, caused by displacement of the uterus, and cured by reposition of that organ. The same authority, in a paper read to the London Congress, advanced the opinion that the exciting cause of attacks of hysteria and hystero-epilepsy was a distortion of the uterus produced by a flexion of the organ upon itself, either forward or backward. He believed the attacks were the result of reflex irritation. He recited

eighteen cases, all of which were relieved. Flechsig¹ favors the gynæcological treatment of hysteria, including castration or oöphorectomy. He reports three cases with good results. His article favors the idea that any morbid condition of the genital organs present ought to be remedied before treating the hysterical symptoms. Zeuner,² on the other hand, refers to a number of cases in which gynæcological treatment gave either entirely negative results or was productive of positive injury to hysterical patients. He quotes Perreti,³ physician to an asylum for the insane, who gives the details of a number of cases in which gynæcological examinations or treatment were directly productive of injury. He mentions a case of a female patient who had delusions and hallucinations of a sexual type in which the physician was the central figure. He reports cases in which proper constitutional treatment, without gynæcological interferences, led to a full recovery. Playfair, also quoted by Zeuner, states that he has often known the condition of hysterical patients to be aggravated by injudicious gynæcological interference. Oöphorectomy will be more fully discussed under HYSTERO-EPILEPSY.

HYSTERO-EPILEPSY.

By CHARLES K. MILLS, M. D.

DEFINITION.—Hystero-epilepsy is a form of grave hysteria characterized by involuntary seizures in which the phenomena of hysteria and epilepsy are commingled, and by the presence in unusual number and severity, between the paroxysms, of symptoms of profound and extensive nervous disturbance, such as paralysis, contracture, hemianæsthesia, hyperæsthesia, and peculiar psychological disorders.

SYNONYMS.—Hystero-epilepsy has long been known under various names, as Epileptiform hysteria, by Loyer-Villermay and Tissot; as Hysteria with mixed attacks, by Briquet; as Hysteria major or Grave hysteria, by Charcot. The term hystero-epilepsy has been used with various significations, and often without due consideration, and for these reasons some authorities advise that it should not be used at all. Gowers,¹ for instance, refers to epileptic hysteria, hysterical epilepsy, and hystero-epilepsy as hybrid terms which tend rather to hinder than to advance the study of the nature of these convulsive attacks and their relations to other forms of hysteria. He holds that it is a clear advantage to discard them as far as possible, and suggests the use of the term hysteroid, as proposed by W. W. Roberts, or that of co-ordinate convulsions, as describing accurately the character of the attack. These suggested terms do not strike me as improvements upon those which he wishes the profession to avoid. The word hysteroid, while good enough in its way, is certainly objectionable on the ground of indefiniteness. Co-ordinate is proposed, because the convulsive movements are of a quasi-purposive appearance; that is, they are so grouped as to resemble phenomena which may be controlled by the will. This meaning of co-ordinate, however, as applied to the disorder in question, would not be easily grasped by the average physician. When it is impossible to name a disease from the standpoint of its pathological anatomy, the next best plan is to use a clinical term which in a plain common-sense manner gives a fair idea of the main phenomena of the affection. Hystero-epilepsy, if it means anything, means simply a disorder in which the phenomena of both hysteria and epilepsy are to some degree exhibited. Certainly, this is what is seen in the cases known as hystero-epileptic. In forming the compound the hysterical element is, very properly, expressed first, the disease being a hysteria with epileptic

¹ *Epilepsy and other Chronic Convulsive Diseases: their Causes, Symptoms, and Treatment*, by W. R. Gowers, M. D., F. R. C. P., etc., London, 1881.

or epileptoid manifestations, rather than an epilepsy with hysterical or hysteroid manifestations. A study of the definition of hystero-epilepsy which has been given will show that it is intended to restrict the application of the term in the present article to cases with involuntary or non-purposive attacks, the voluntary or purposive having been considered in the last article.

HISTORY.—The greatest impulse to the study of hystero-epilepsy in recent years has been given by the brilliant labors of Charcot and his pupils and assistants in his famous service at La Salpêtrière. In his lectures on diseases of the nervous system¹ (edited by Bourneville), and in various publications in *Le Progrès médical* and other journals, Charcot has reinvestigated hysteria major with great thoroughness, and has thrown new light upon many points before in obscurity. He deserves immense credit also for the work which he has stimulated others to do. Bourneville, well known as the editor of some of Charcot's most valuable works, has published, alone or with others, several valuable monographs upon hysteria and epilepsy.² The most valuable work on hystero-epilepsy, however, because the most elaborate and comprehensive, is the treatise of Richer.³ Richer was for a time interne in the Salpêtrière Hospital, and with Regnard pursued his investigations under the superintendence and direction of Charcot. His book is a volume of more than seven hundred pages, containing a vast amount of information and profusely illustrated, in large part by original sketches by the author. Charcot himself has written for it a commendatory preface.

No article on hystero-epilepsy can be written without frequent use of this work of Richer, and also of the numerous contributions of Charcot. To them we are indebted for new ways of looking at this disease, as well as for an almost inexhaustible array of facts and illustrations of the diverse phases of this disorder.

While the curious, grotesque, or outrageous manifestations now known as hystero-epileptic have been discussed with more or less minuteness by authors from the time of Sydenham to the present, usually, and more especially in all countries but France, these manifestations have been studied as isolated phenomena. Charcot and Richer, however, present a comprehensive view of hysteria as a disease of a certain typical form, but often manifesting itself in an imperfect or irregular manner. This regular type is characterized particularly by a frequently- or infrequently-recurring grave attack, which is divided into distinct periods, and these periods into phases.

This regular type of grave hysteria once understood, a place of advantage is gained from which to study the disease in its imperfect, irregular, and abortive forms. Whatever its pathology may be, such striking symptoms as loss of consciousness with spasm, hallucinations, and illu-

sions show at least temporary disturbance of the integrity of the cerebrum.

Hystero-epilepsy of imperfectly developed or irregular type is a not uncommon affection in this country, but the disease in its regular type is comparatively rare.

VARIETIES.—Hysteria and epilepsy, so far as seizures are concerned, may show themselves in two ways in the same patient; but I believe that it is best that the term hystero-epilepsy should be restricted in its application, as Charcot, Bourneville, and Richer have advised, to the disorder in which hysterical and epileptic symptoms are commingled in the same attack—what is spoken of by the French as hystero-epilepsy with combined crises. The other method of combination is in the affection known as hystero-epilepsy with separate crises, in which the same patient is the victim of two distinct diseases, hysteria and epilepsy, the symptoms of which appear independently of each other.

The fact that hysteria is at times associated with true epilepsy is often overlooked. A patient who is known to have had pure hysterical seizures of the grave type has also a genuine paroxysm of epilepsy, and thus the medical attendant is deceived. I will dismiss the consideration of hystero-epilepsy with separate crises with a few paragraphs at this place, devoting the rest of the article to the disorder with combined crises.

The coexistence of hysteria and epilepsy, with distinct manifestations of the two neuroses, has been most thoroughly considered by D'Olier.¹ Beau in 1836, and Esquirol in 1838, first showed this coexistence. Landouzy in 1846 first made use of the name hystero-epilepsy with separate crises.

In France the distinct existence of hysteria and epilepsy in the same individual is not, according to D'Olier, a very exceptional fact. Beau has reported it 20 times in 276 cases. The different modes of coexistence have been summed up by Charcot as follows: "1, Hysteria supervening in a subject already epileptic; 2, epilepsy supervening in a subject previously hysterical; 3, convulsive hysteria coexisting with epileptic vertigo; 4, epilepsy developing upon non-convulsive hysteria (contracture, anæsthesia)."

The following case, now in the Philadelphia Hospital, illustrates the first of these modes of combination: S—, aged thirty-nine, female, a Swede, came to this country in 1869. She said that her mother had fits of some kind. The patient had her first fit when she was four years old. Her menses did not come on until she was nineteen. With the appearance of her periods she had fainting-spells off and on for two years, and in these spells she would fall to the ground. After two years she improved somewhat, but still would have an occasional seizure like petit mal. Four years ago she had a severe fit, in which she bit her tongue. This was a paroxysm of true epilepsy. It was witnessed by the chief nurse in the hospital, a competent observer. Since then she has had attacks of some kind every month or oftener. She rarely had a true epileptic seizure. Often, however, she had hysterical and hystero-epilep-

¹ Memoir which obtained the Esquirol prize in 1881, by M. D'Olier, interne of the hospitals of Paris, on "Hystero-Epilepsy with Distinct Crises, considered in the Two Sexes, and particularly in Man," translated and abstracted by E. M. Nelson, M. D., in the *Alienist and Neurologist*, April, 1882.

tic attacks. These paroxysms have been witnessed by myself and by the resident physician and nurse. Rarely they were epileptic, frequently they were hysterical. Mental excitement will often induce an hysterical spasm.

PATHOLOGY.—Holding that hystero-epilepsy is a form of grave hysteria, the remarks which have been made in the last article on the probable nature of severe convulsive attacks will be applicable here. In hystero-epilepsy with the typical grave attack we have the highest expression of that disturbance of cerebro-spinal equilibrium which constitutes the pathology of hysteria.

ETIOLOGY.—It will also be unnecessary to go at length into the discussion of the predisposing and exciting causes of hystero-epilepsy. In general, its predisposing causes are those of hysteria of any form. Certain causes or conditions, however, predispose to certain types or forms of hysteria. The Latin races are more inclined to the hystero-epileptic form of hysteria than are the natives of more temperate or colder climates. Bearing upon this point, I have already quoted the letter of Guiteras with reference to hysteria and hystero-epilepsy in Cuba and semi-tropical America. Forms of religion which cultivate to an extreme degree the emotional or the sentimental side of human nature tend to produce hystero-epilepsy.

With reference to sex it may be said that hystero-epilepsy prevails to a greater extent among females than males, even proportionately to a larger degree than some of the other marked phases of hysteria. It does, however, occur in men and boys, although rarely. Richer records, from the practice of Charcot, a case in a lad of twelve years. Several cases have fallen under my own care.

Ten years since I saw a case of hystero-epilepsy, which in some respects closely simulated tetanus, in a youth nineteen years old. He was well until seventeen years of age, when he slightly wrenched his back. Shortly afterward he felt some pain between the shoulders. From that time, at irregular intervals, generally of a few days only, he was subject to attacks of dull pain, which seemed to run up the spine to the head. About two months after this injury he first had a spasmodic attack. A spasm would come on while he was quietly sitting or working. The body assumed the backward-arched position. As his father described the case, there was always space enough under his back for a baby to crawl through. Generally, he would have more than one seizure on a given occasion. He would sometimes have as many as six or seven in one hour. On coming to, he would stare and mutter and work his mouth and lips, at the same time pointing around with his hands and fingers in a wild way. Sometimes he would sleep for several hours afterward if not disturbed, but his sleep was not of a stertorous character. He said that he could feel the attacks coming on; his body felt as if it was stretching, his head going back. He thought he was not conscious during the whole of the attacks, but between the spasms he could take medicine when directed. When first examined he had decided tenderness on pressure over the second, third, and fourth dorsal vertebrae. Pressure in this region would sometimes bring on a convulsive paroxysm. When first seen he had been for three months having seizures every two or three weeks. He was under observation for several months, during which time he was treated with faradization to the spine, the hot spinal douche, tonics, and bromides, and made a complete recovery.

W. Page McIntosh¹ has reported several cases of hystero-epilepsy in the male, one of which is doubly interesting because it was in a negro. This patient was twenty-one years old, stout, and previously in good health. He complained of intense pain in the stomach, and soon passed into a violent convulsion. To show the importance of diagnosis in these cases, it is interesting to note that the doctor first thought of strychnia-poisoning, then of acute indigestion, next of tetanus. Soon, however, he decided that he had a case of hysteria. The patient had other convulsions on the day following the first attack. The seizures were evidently hystero-epileptic or hysterical. He was not unconscious, and believed that on a recent previous evening he had been conjured by an old negress. The spell was to work in three days, which it did. The doctor counter-spelled him with a hypodermatic syringe, after which he promptly recovered. McIntosh reports another case in a man forty years old and the father of six children, who was laboring under strong mental excitement because of the sufferings of a dangerously ill child. His whole form was convulsed, and his body underwent a variety of peculiar contortions. He had had similar attacks before, and had subsequent recurrences.

The following case was observed in the Philadelphia Hospital: W. F.—, aged twenty-eight years, married, has one child. His seizures began seven years ago, when he had an attack while playing a game of pool. At this time he had, according to his account, a sudden feeling of giddiness or vertigo in which he fell over and had a spasm, during which he thinks he was unconscious. After the seizure he suffered from headache, but had no disposition to sleep.

From that time until the present he has been subject to these spells, though the paroxysms are very irregular in frequency. Sometimes he will have several attacks in a day; again, he will be free from them for days, and perhaps for two or three weeks, but never for more than a month at a time. They have come on him while walking in the street, and on several occasions he has been taken to different hospitals. He was admitted to the Philadelphia Hospital four times. On his first admission he only remained over night; on his second and third he remained for two or three weeks. On the last admission he remained four weeks, and had spasms every day and night after admission. He had, by actual count, from five to six hundred after he went in; and in one evening, from seven P. M. to midnight, he had no less than thirty-eight. These seizures, which were witnessed by myself and two resident physicians, differed but little from each other, although at times some were more violent than others. They began with a forced inspiration; then the patient straightened himself out and breathed in a stertorous or pseudo-stertorous manner. The pulse in that stage became slow, and at times was as low as 48 per minute. The temperature was normal or sub-normal. The arched position was sometimes taken, but the opisthotonos was not marked. The paroxysm ceased by an apparent forced expiration, and the breathing then became normal; the patient remained in a somewhat dazed condition, which was only momentary. During the attack the patient said that he was unconscious of his surroundings. In the interval between the attacks he suffered from headache and from pain

¹ *Med. News*, vol. xlviii., No. 1, Jan. 2, 1886, pp. 5-8.

over the region of the stomach. He also had tenderness on pressure over the lumbar vertebræ. He never bit his tongue.

Age has some influence in the development of hystero-epilepsy. It is of most common occurrence at the period of pubescence; it is rare in old age, but occurs with comparative frequency in middle life; or, rather, it should be said that middle-aged hystero-epileptics are not uncommonly met with, individuals who have for many years been subject to the attacks. In young children, girls or boys, it is certainly rare.

With reference to the exciting causes of hystero-epilepsy, it will only be necessary to say that of those which have already been enumerated in the general discussion of the etiology of hysteria, a few, such as domestic troubles, abnormal sexual excitement, and painful menstruation, are likely to induce the paroxysm, but fright, excitement, anxiety, sudden joy, and other psychical disturbances are the most frequent of the exciting causes of the seizures. A threat or a blow has been known to precipitate an attack. The use or abuse of alcohol is sometimes an exciting cause. Reflex irritation, such as that from intestinal worms, and digestive disorders sometimes produces hystero-epileptic attacks in children.

SYMPTOMATOLOGY.—In considering the symptoms of hystero-epilepsy the subject must be approached from several points of view. In the first place, the disorder can be divided (1) into the regular or typical grave attack; and (2) into the irregular attacks. These irregular seizures can be greatly subdivided, but their discussion will be confined to those types which have been most observed in this country, although I do not think that any variety of hystero-epilepsy is distinctively American; and this is what might be supposed from the largeness of our country and the different nationalities of which it is composed.

I have seen but few cases of hystero-epilepsy of the regular type. One of these was first described at some length in the *American Journal of Medical Sciences* for October, 1881. I will here give the case, with illustrations, somewhat condensed from the accounts as first published.¹

R—, æt. 21, single, was first admitted to the German Hospital Nov. 13, 1879. Between her ninth and twelfth years she had had several attacks of chorea. During childhood she was often troubled with nightmare and unpleasant dreams; she often felt while asleep as if she were held down by hands. She was frequently beaten about the head and body. Her menses did not appear until she was nearly eighteen. Before and at her first menstrual epoch she suffered severe pain and cramp. During the first year of her menstruation, while at Atlantic City, the flow appeared in the morning, and she went in bathing the same afternoon. She stayed in the water two hours, was thoroughly chilled, and the discharge stopped. Ever since that time she had only menstruated one day at each period, and the flow had been scanty and attended with pain. When about eighteen she kept company with a man for five months, and after having put much confidence in him learned that he had a wife and two children. This episode caused her much worryment. She positively

¹For the opportunity of studying and treating this case I was under obligations to Charles S. Turnbull and J. Solis Cohen, the patient having been for several months under their care at the German Hospital of Philadelphia. Carefully prepared notes of the case were furnished to me by H. S. Bissey and H. W. Norton, resident physicians at the hospital. I was also under great obligations to my friend J. M. Taylor for a series of sketches of the positions assumed by the patient at different stages of the attack.

denied seduction. She became much depressed. September 2, 1879, she was seized in a street-car with a fainting fit. On coming to, she found her left arm was affected with an unremitting tremor. Seven weeks later she was admitted to the German Hospital. She had severe spasmodic attacks, and the diagnosis of hysteria was made. She remained in the hospital about four weeks. On leaving she again went into service. She was readmitted June 9, 1880, in an unconscious or semi-conscious condition. She had been on a picnic, and while swinging was taken with an attack of spasm and unconsciousness. During two hours after admission she had a series of convulsions. After this she had similar attacks two or three times a week, or even oftener.

I first saw her about the middle of January, 1881. She had an hysterical face, but was possessed of considerable intelligence, and when questioned talked freely about herself. The most prominent physical symptom that could be discovered was a large tremor, affecting the left arm, forearm, and hand. This was constant, and had been present since her admission to the hospital. The left half of her body was incompletely anæsthetic, the anæsthesia being especially marked in the left forearm. Ovarian hyperæsthesia could not at this time be made out. She was, however, hyperæsthetic over the occipital portion of the scalp and the cervico-dorsal region of the spine. Pressure or manipulation of these regions would in a few moments bring on an attack of spasm. The attacks, however, usually occurred without any apparent exciting cause.

For a period of from six to twelve hours before an attack she usually felt dull, melancholy, and strange in the head. Frequently she had noises like escaping steam in her ears, but more in the right ear than in the left. She complained of cardiac palpitations. She usually had pain in the small of her back. Her limbs felt weak and tired. Just as the attack was coming on her eyes became heavy and misty, her head felt as if it was sinking backward, and if not supported she would fall in the same direction.

On several occasions I had the opportunity of watching every phase of the attack or series of attacks, the spasms continuing sometimes from one to four or five hours. The order of events was not always the same, and yet a general similarity could usually be seen in the successive stages of

FIG. 18.

the phenomena. I will try to give an outline of the different stages and phases as observed on an occasion when the seizures were severe.

After lying down, the first noticeable manifestation was a twitching of

the eyelids and of the muscles of the forehead and mouth. Her head was next moved from side to side, and she looked around vaguely. Respiration became irregular. In a few moments a convulsive tremor passed down her body and limbs. Her arms were now carried outward slightly from the body, the hands being partly clenched. The lower extremities were straightened, the left foot and leg being carried over the right (Fig. 18). Her limbs were rigid. Her mouth was closed, the teeth being

FIG. 19.

ground together. Consciousness was lost, and respiration seemed to stop.

A series of strong convulsive movements next ensued. Her entire

FIG. 20.

body was tossed up and down and twisted violently from side to side. Sometimes she assumed a position of opisthotonos. Her whole body was then again lifted and hurled about by the violence of the movements. A

few seconds later she became quiet but rigid, in the position shown in Fig. 19, corresponding to the position of crucifixion of the French writers.

Soon she assumed the position represented by Fig. 20, and the convulsions were renewed with violence, the patient's limbs and body being frequently tossed about and the latter sometimes curved upward. After these movements had continued a brief period the patient became calm and partially relaxed; but the respite was not long. A series of still more remarkable movements began, chiefly hurling and lifting of the body. Eventually, and apparently as a climax to a succession of efforts directed to this end, she sprang into the position of extreme opisthotonos represented in Fig. 21. This sketch, by Taylor, is a very faithful view of her exact position. She remained thus arched upward for a minute, or even more. A series of springing and vibratory movements followed, the body frequently arching.

FIG. 21.

As the spasms left she sat up on her bed, and at first looked around with a bewildered expression. She turned her head a little to one side and seemed to gaze fixedly at some object. Her expression was slightly smiling. When spoken to she looked straight at the one addressing her, but without appearing to know what was said, and the next moment the former position and attitude were resumed. After a few minutes she lay down muttering incoherently, and in about a quarter of an hour fell asleep.

I have simply described one attack. Sometimes she would have several in succession, or the spasmodic manifestations would be repeated several times in a regular or an irregular manner. Strong pressure in the ovarian regions usually would not cut short the spasms. They could be stopped, however, by etherization or by active faradization of the limbs or trunk. She did not always conduct herself in the same manner in the period which succeeded the spasms. Sometimes, after getting into the sitting posture, instead of smiling, she would look enraged and speak a few words. The following expressions were noted on one occasion: "You know it! Yes, you do! Yes! yes!" Often she was heard to mutter for hours after the attack. Her lips would sometimes be seen to be moving without any words being heard. Sooner or later she would fall into a sound sleep which would last several hours.

During the spasms she seemed to be entirely unconscious of her surroundings. To a looker-on her movements seemed sometimes to have the appearance of design, but I soon convinced myself that such was not the case. She was insensitive to painful or other impressions. Her expression was blank and unchanging. She said that the only thing that she remembered about the attacks was that she heard a strange, confused sound; this was most probably just as she was returning to consciousness.

Numerous remedies were tried without any apparent effect. These included sodium and potassium bromides, iron, zinc salts, physostigma, cimicifuga, camphor, ether, etc. A uterine examination was made, but nothing especially calling for local treatment was found. She was placed upon equal parts of tincture of valerian and tincture of iron in half-teaspoonful doses three times daily. Capsules of apiol were also ordered to be taken three times daily just before and during her menstrual period. Her menses became more profuse and continued longer. The attacks began to diminish in frequency, and became less severe. In March, not having had a seizure for several weeks, she left the hospital and again went into service. Six months elapsed and she had no attack. She reports occasionally at my office. She says that she feels entirely well. The tremor of the left upper extremity entirely disappeared. She continued to take valerian and iron for four months, but stopped the apiol after the second or third menstrual period.

With this case before us the phenomena of the disease can be more readily grasped. I will necessarily make free use of the labors of Richer in my description of symptoms.

Hystero-epileptic attacks usually, although not always, have distinct prodromes. These have been more thoroughly studied and reported by Richer than by any other author. They are classed by him under the four heads of psychological affections, including hallucinations, affections of the organic functions, motor affections, and affections of sensibility. The patient's condition is changing; she is listless, irritable, melancholy, despairing, slovenly. Sometimes she is noisy, sometimes mute. At times she is full of wild excitement. Hallucinations of sight sometimes come on at this period—most commonly visions of cats, rats, spiders, etc. These visions of animals, as first pointed out by Charcot, in passing before the patients run from the left to the right or from the right to the left, according as the hemianæsthesia is situated on the left or on the right. Hallucinations of hearing, as of music, threats, demands, whistling, trumpeting, etc., also occur, chiefly on the hemianæsthetic side. These hallucinations are worse at night. Sometimes at night the patients are the victims of imaginary amours. Want of appetite, perverted taste, nausea and vomiting, flatulence, tympanites, pyalism, unusual flow of urine, feelings of oppression, hiccough, laughing, barking, loss of voice, palpitation of the heart, and flushings are among some of the many disorders of the organic functions which are sometimes present during the prodromal period. Loss of muscular power or a species of ataxia, peculiar limited spasmodic movements, contracture, first of one limb and then of another, may be observed. Charcot, Bourneville, Regnard, and Richer, all give admirable illustrations of different forms of contracture. In one case the right arm and wrist are flexed,

and the hand held at the level of the shoulder with fingers extended. Anæsthesia—total, unilateral, or local, tactile, of pain, temperature, etc.—may also occur. Sometimes achromatopsia or color-blindness shows itself; sometimes deafness in one ear is present. Tenderness over the ovarian region is often an immediate precursor. To Charcot we owe the most careful study of these symptoms.

Among the most interesting prodromic affections of sensibility are the hysterogenic or hystero-epileptogenic zones. These have been well studied and described by Richer, from whose work Figs. 22 and 23 have been taken. Brown-Séquard has shown that animals rendered epileptic by lesions of the spinal cord, medulla oblongata, or nerves are sometimes attacked with convulsions spontaneously, but it is also possible to provoke these attacks by exciting a certain region of the skin which he designates as the epileptogenic zone. This zone, situated on the same side of the body as the nervous lesion, has its seat about the angle of the lower jaw, and extends toward the eye and the lateral region of the neck. The skin of this region is a little less sensitive than that of the opposite side, but touching it most lightly provokes epileptic convulsions. The simple act of breathing or blowing on it brings about the same result.

Something analogous to this epileptogenic zone has been noticed among hystero-epileptics, and has been pointed out by several writers. Richer gives the particulars of a number of cases. In one patient the hyperæsthetic zone was between the two shoulder-blades. Simply touching this region was sufficient to provoke an attack, and this was more easily done if near the time of a spontaneous seizure. After the grave attacks the excitability would seem to be exhausted, and pressure in the zone indicated would not cause any convulsive phenomena. A second case presented a similar condition. If touched over the dorsal spine between the shoulders, she felt a violent pain in the belly, then a sense of suffocation, which brought on at once loss of consciousness. In a third patient the hysterogenic zone was different. It was double. It was necessary to touch two symmetrical points situated to the outside and a little below the breasts in order to bring on the hystero-epileptic convulsions. Touching one of these points did not produce any result. Other cases are given in detail, but a glance at the two figures (22 and 23) will show some of the principal hysterogenic zones both for the anterior and posterior surfaces of the body. A zone of ovarian hyperæsthesia was common to all the patients. It did not differ essentially from the other hysterogenic zones. If the ovarian hyperæsthesia existed along with other hysterogenic points, the excitation of the ovarian region was always the most efficacious. The hysterogenic zones always occupy the same place in the same case. They are found on the trunk exclusively; they are more frequently in front than behind; in front they occupy lateral positions, and are often double and symmetrical; behind they are more often single and median; they exist more frequently to the left than to the right, and the unilateral zones have always been met with on the left side.

The hysterogenic zones bear no constant relation to the hemianæsthesia. It is true that the ovarian pain is most often seated on the hemianæsthetic side, but sometimes it is present on the opposite side. They

are not at all times equally excitable. They are more so when the convulsive attack is imminent.

Ovarian pressure gives rise to the spasmodic attacks: the same pressure arrests them. What is true of ovarian compression is equally true of all the hysterogenic zones. A light touch brings on the convulsions,

FIG. 22.

Principal Hysterogenic Zones, anterior surface of the body: *a, a'*, supramammary zones; *b*, mammary zones; *c, c'*, infra-axillary zones; *d, d', e, e'*, inframammary zones; *f, f'*, costal zones; *g, g'*, iliac zones; *h, h'*, ovarian zones (after Richer).

which have scarcely commenced when they can be stopped by a new excitation of the same point.

As already stated, the attack of hystero-epilepsy, having fully begun, is divided by Richer into distinct periods. Although these are seldom seen in perfection, it is necessary to have some clear idea of their phe-

nomena in order to view the affection comprehensively. They were seen well developed in the case given. These periods are—(1) The epileptoid period; (2) the period of contortions and of great movements; (3) the period of emotional attitudes; (4) the period of delirium.

In the first or epileptoid period of the hystero-epileptoid attack, which

FIG. 23.

Principal Hystero-genic Zones, posterior surface of the body: *a*, superior dorsal zone; *b*, inferior dorsal zone; *c*, posterior lateral zone (after Richer).

receives its name from its resemblance to true epilepsy, various phases always reproduce themselves in the same order. Loss of consciousness and arrest of respiration, muscular tetanization in various positions, followed by clonic spasms, and, finally, muscular resolution, are the successive phenomena of this period, which usually lasts several minutes. Loss of consciousness is complete during this period. Muscular tetan-

ization shows itself in movements large and small, sometimes of the whole body. The trunk may become as stiff as a bar of iron; the face is sometimes cyanosed, puffed; froth even appears, which it is well to remember, as this is considered by some as absolutely diagnostic of epilepsy. Many positions may be assumed. The important significant features of the tonic phase of period are muscular tetanization with loss of consciousness and respiratory spasm. In the clonic phase movements at first rapid and short, later larger and more general, ensue, and are accompanied by whistling inspiration, jerking expiration, hiccoughs, noisy deglutition. The phase of muscular resolution comes on, in which the patient completely relaxes; sometimes a true stertor occurs. The epileptoid period usually lasts altogether several minutes, the first two phases usually occupying about one minute.

In the period of contortions and great movements wonderful attitudes and contortions are observed in one phase, and in another great movements. One of the attitudes particularly fashionable with hysteropileptics is the arched position, in which the body is curved backward in the form of an arch so as to rest only on the head and feet. Sometimes the patient may rest on the belly or side, the remainder of the body preserving its curved position; the body may indeed assume almost any strange and seemingly impossible attitude. The so-called great movements are executed by the entire body or by a part of the body only; they are of great variety; sometimes they are movements of salutation; sometimes the semiflexed legs are projected upward, etc. Often the phase of great movements is marked at its beginning by a piercing cry; loss of consciousness is not the rule.

The period of emotional attitudes or statuesque positions is the most dramatic stage of a highly dramatic disease. Hallucinations ravish and transport the patient: sometimes they are gay, sometimes they are sad. The dramatic positions assumed are in consonance with the patient's hallucinations. The patient reproaches, opposes, supplicates, is angry, is furious; she assumes positions of supplication on her knees, becomes menacing, and even strikes. In the great works of Bourneville, of Regnard, and of Richer many cases are related at great length and with vivid details. Camera and pencil are frequently called in to assist the pen in presenting scenes which read as if drawn from an exciting drama or novel. Among the expressions and attitudes which they have succeeded in photographing are those illustrating emotions of menace, appeal, amorous supplication, erotism, ecstasy, mockery, beatitude.

After the period of the emotional attitude consciousness returns, but only in part, and for a time the patient remains a prey to a delirium whose character varies. This delirium may be concerned with subjects the most varied; it may be gay, sad, furious, religious, or obscene. It is mingled with hallucinations; voices are heard; sometimes are seen personages who are known; sometimes the scenes are purely imaginary. During this fourth period the patients will sometimes make the most astounding statements and accusations. They will wrongfully charge theft, abuse, etc. upon others; they believe in the reality of their hallucinations, and, what is more important, they will sometimes persist in this belief after the attack is over. The third and fourth periods are sometimes confounded. When the four periods described succeed each other in

order, they constitute a regular and complete attack of hystero-epilepsy.

By comparing the notes upon the case detailed with the description given of the typical hystero-epileptic attack, it will be seen that the different periods, and even the phases, can be made out with but little difficulty. After a few moments of convulsive movements and irregular breathing the patient was attacked with muscular tetanization, arrested respiration, and loss of consciousness. Tonic convulsions followed, and then immobilization in certain positions. Next came the clonic spasms and resolution. In the period of contortions the arched position is one more extreme than any represented by the illustrations of the French authors, although it is closely approximated by some of their illustrations. After this position of opisthotonos had been taken a succession of springing and lifting movements occurred, probably corresponding to the phase of great movements. The period of emotional attitudes was very clearly represented by the position assumed, the expression of countenance, and sometimes by the words uttered. Even the period of delirium was imperfectly represented by the mutterings of the patient, which were sometimes long continued after the attack.

A beautiful illustration of one of the positions assumed by a hystero-

FIG. 24.

epileptic is shown in Fig. 24 from Allan McLane Hamilton's treatise on *Nervous Diseases*. The patient, æt. eighteen, represented in the figure had suffered from hystero-epileptic attacks since the beginning of the menstrual period. Usually, she had severe but distinct epileptic seizures, and afterward an hystero-epileptic paroxysm. The muscles of her back were rigidly contracted in opisthotonos. Her arms were drawn over her chest, and her forearms slightly flexed and crossing each other. Her thumbs were bent in and covered by her other fingers, which were rigidly flexed. Her toes were also flexed, and her right foot presented the appearance called by Charcot *le pied bot hystérique*, or hysterical club-foot.

As has already been stated, hystero-epilepsy of irregular, imperfect, or abortive type is most commonly observed in this country, or at least in the Middle States, of which my own knowledge and experience are greatest. As has been demonstrated by Richer and Charcot, the irregular type may be of any form, from a paroxysm with a scarcely detectible convulsive seizure and scarcely recognizable loss of consciousness up to

frightful attacks which from their terrible nature have been termed demoniacal, and in which occur the wildest phenomena of movement, frightful contortions and contractions, with grimaces and cries of fury and rage. Sometimes the movements show a violence beyond description. These frightful seizures are of extreme rarity in America. Sometimes attacks of ecstasy or attacks of delirium are the predominating or almost the only feature. The epileptoid attack, so far as my experience has gone, is the most prevalent variety of hysterо-epilepsy. Epileptoid attacks are simply the result of the predominance and modification of the first or epileptoid period of the typical grave attack. Richer has described several varieties.

I have seen a number of cases of the epileptoid variety or other irregular forms. These cases have presented a few or many of the symptoms of grave hysteria, such as anæsthesia, analgesia, hyperæsthesia, blindness, aphonia, paralysis, contracture, etc., and have also had attacks of tonic and clonic spasm, with complete or partial loss of consciousness. The phenomena of the periods of contortions and great movements, of emotional attitudes, and of delirium have been, however, altogether or almost entirely absent. These epileptoid attacks have varied somewhat in different cases.

The following are the notes of three cases observed by me:¹

M—, æt. twenty-seven, a widow, admitted to the Philadelphia Hospital February 4, 1882, was married thirteen years before, when only fourteen years of age, and remained in comparatively good health for four years after her marriage, during which time she had three children, all of whom died in early infancy. Four years after her marriage, while carriage-riding, she for the first time had a spasm. According to her story, the seizure was very severe; she lost consciousness, and passed from one spell into another for an hour or more. She had a second attack within two weeks, and since has had others at intervals of from one week to three or four months. Four years ago she passed into a condition of unconsciousness or lethargy in which she remained for three days. On coming out of this state she found that the left half of her body was paralyzed and that she was speechless. In two weeks she recovered her speech and the paralysis disappeared. On June 15, 1881, she gave birth to a male child. On the night of the 16th she became delirious, and on the 17th she again lost her speech and had a paralytic seizure, the paralysis now affecting both legs. She recovered her speech in a few days, but the paralysis remained. Her babe lived, and with her was admitted to the hospital. He had had seven attacks of spasm at intervals of about a month. The patient's mother was for a time insane, and had been an inmate of an insane asylum for some months since her first epileptiform attack.

She was carefully examined on the day of her admission. She was bright, shrewd, and observant. She gave an account of her case in detail, and said she was a puzzle to the doctors. Both legs were entirely helpless, the feet were contracted in abduction and extension, assuming the position of talipes equino-varus; the legs and thighs were strongly extended, the latter being drawn together firmly. The left upper extremity was distinctly weaker than the right, but all movements were retained. She

¹ Published in *Journal of Nervous and Mental Disease*, vol. ix., No. 4, October, 1882.

had no grasping power in the left hand. She was completely anæsthetic and analgesic below the knees, and incompletely so over the entire left half of the body. Pain was elicited on pressure over the left ovary and over the lower dorsal and lumbo-sacral region of the spine. Both knee-jerks were exaggerated.

I lectured on this patient at my clinic at the hospital, stating that I believed the case to be one of hystero-epilepsy, and only needed to see an attack of spasm to confirm the diagnosis. Up to this time she had not had a seizure since admission. She had, however, been complaining for several days of peculiar sensations in the head and of severe headache. She had also been more irritable than usual, and said that she felt as if something was going to happen to her. The same afternoon, Dr. Rohrer, the resident physician in charge of the patient, was sent for, and found her in a semi-conscious state. She did not seem to know what was going on around her, but was not in a stupor. Her pulse was 114 to 120; respirations were 20 to 22, regular. The corneæ responded on being touched. Some twitching movements of the eyeballs and eyelids were noticed; the thumb and forefinger of the left hand also moved, as if rubbing something between them.

In a few moments an epileptoid paroxysm ensued. She became unconscious and rigid. The lower extremities were strongly extended in the equino-varus position already described. The arms were extended at her sides, the wrist being partly flexed and rotated outward, the hands clenched. Her face, at first pale, became deeply congested. Her trunk became rigid in a position of partial opisthotonos. Brief clonic spasms followed, then resolution, the whole seizure not lasting more than from two to three minutes. She lay for a minute or two unmindful of anything or anybody, and then sat up and looked around wildly. She dropped back again and began to mumble, as if she wished to speak, but could not. Paper and pencil were given to her, and she wrote that she was conscious, but could not speak. Her temperature, taken at this time, was 99.8° F.

Attacks similar to the one just described occurred at irregular intervals for two days. On their cessation she was speechless, and the permanent symptoms already detailed—the anæsthesia, paralysis, etc.—were deepened. During the attacks but little treatment was employed; hypodermic injections of morphia and potassium bromide by the mouth were, however, administered. After the attack the valerianate of iron by the mouth, faradization of the tongue, and galvanization of the legs below the knees with weak currents, were ordered. Her speech returned in a week. For about a month she showed no other signs of improvement; then she began to mend slowly, gradually using her limbs more and more. On May 11, 1882, she was discharged, and walked out of the hospital with her child in her arms, apparently perfectly well. During the last month of her stay no treatment was used but mild galvanization every other day.

Mrs. A——, æt. forty-five, was seen by me in consultation. For some months at her menstrual period she had been out of sorts. At times she had had hallucinations of sight. For several weeks she had been troubled more or less with a feeling of numbness and heaviness in the left arm and leg, particularly in the latter, and also with diffused pain in the head and

a sensation of aching and dragging in the back of the neck. For three weeks, off and on, she had had diarrhœa, which had weakened her considerably. She awoke one morning feeling badly and yawning every few minutes. She passed into a condition of unconsciousness with attacks of spasm. I did not see her on this the first day of her severe illness, but obtained from the physician in attendance some particulars as to the character of her seizures. Evidently the condition was similar to that presented by the last case, that described by Richer as the epileptoid status, in which tonic and clonic spasm and resolution are repeated again and again. Attack after attack occurred for nine or ten hours, sometimes one immediately following another, sometimes an interval of several minutes or of half an hour or more intervening. Respiration was partially arrested. Tonic spasm predominated; the limbs became rigid in various positions; sometimes the neck and trunk were strongly bent backward, producing partial opisthotonos. While the body and limbs remained tetanized they were thrown into various positions (clonic phase of an epileptoid attack). Although she answered questions addressed to her by her physician between the spells, she did not recognize him until evening, after the spasms had ceased, and then was not aware that he had been in attendance during the day, although he had been with her almost constantly. Leeching and dry cupping to the back of the neck were employed, and potassium bromide and tincture of valerianate of ammonia were given.

Early on the morning of the next day she had another attack of unconsciousness and spasm, in which I had the opportunity of seeing her. The spasm amounted only to a slight general muscular tetanization. The whole attack lasted probably from half a minute to a minute. The following day, at about the same hour, another paroxysm occurred, having a distinct but brief tonic, followed by a clonic, phase, in which both the head and body were moved. The next day, also at nearly the same hour, she had an attack of unconsciousness or perverted consciousness without spasm. She had a similar seizure at 4 P. M. For two days succeeding she had no attacks; then came a spell of unconsciousness. After this she had one or two slight attacks, at intervals of a few days, for about two weeks.

Between the attacks the condition of the patient was carefully investigated. On lifting her head suddenly she had strange sensations of sinking, and sometimes would partially lose consciousness. She complained greatly of pain in the head and along the spine. Her mental condition, so far as ability to talk, reason, etc. was concerned, was good, but any exertion in this direction easily fatigued her and rendered her restless. She had at times hallucinations of animals, which she thought she saw passing before her from left to right. The left upper and lower extremities showed marked loss of power. The paralysis of the left leg was quite positive, and a slight tendency to contracture at the knee was exhibited. She was for two weeks entirely unable to stand. The kneejerks were well marked. Left unilateral sweating was several times observed.

A zone of tenderness was discovered in the occipital region and nape of the neck, and she had also left ovarian hyperæsthesia. Left hemianæsthesia was present, head, trunk, and limbs being affected. She complained of dimness of vision in the left eye, and examination by the

attending physician and myself showed both amblyopia and achromatopsia; she was unable to read print of any size or to distinguish any colors with the left eye, although she could tell that objects were being moved before the eye. A distinguished ophthalmologist was called in consultation. An ophthalmoscopic examination showed a normal fundus. Each eye was tested for near vision. It was found that she could read quite well with the right eye, and not at all with the left. While reading at about sixteen inches a convex glass of three inches focus was placed in front of the right eye, but she still continued to read fluently. A few minutes later, however, on retesting, she could not read or distinguish colors with the left eye. Sometimes toward evening her feet would become slightly oedematous. Examination of the urine showed neither albumen nor sugar. The heart-sounds were normal.

Owing to the apparent periodicity of the attacks quinine in large doses was administered, and seemed to act beneficially. In addition, valerianate of zinc and iron, strychnia, and other nerve-tonics were used in her subsequent treatment. Applications of faradic electricity, both with the metallic brush and the moist sponges, were made every other day. She was persistently and strongly encouraged as to the certainty of her recovery. Her paralysis, anaesthesia, etc. gradually disappeared, and in little more than two months she was able to leave home and go to the country. She has since remained well, but is more easily fatigued than formerly, and does not feel as strong in the left side of her body as she did when in perfect health. At her menstrual period she becomes very nervous.

M—, æt. twenty-three, a well-educated young lady,¹ in the autumn of 1880 had nursed her mother faithfully through a serious illness. She became anæmic and nervous. Choreic twitchings and occasional slight spasms were the first symptoms that alarmed her family. The spasms came on apparently from any over-exertion. Gradually they became a little more severe in character. Under rest-treatment, with gentle massage, tonics, and steady feeding, in six weeks she greatly improved. A few weeks later, however, she again relapsed, and became worse than she had ever been. The spasms returned with greater force and frequency. She became unable to walk, or could only walk a few steps with the greatest difficulty, although she could stand still quite well. On attempting to step either forward or backward her head, shoulders, hips, and trunk would jerk spasmodically and she would appear to give way at the knees. No true paralysis or ataxia seemed to be present, but locomotion was impossible, apparently because of irregular clonic spasms affecting various parts of her body. Eventually she became extremely hyperæsthetic in various regions (hysterogenic zones), along the spine, beneath the breasts, in the ovarian area, etc. The slightest pressure or any applications of heat or cold, electricity, etc. would generally bring on an attack of spasm.

While trying to apply galvanism on one occasion she suddenly complained of nausea, and her expression changed, becoming somewhat fixed.

¹ This patient was for a long time under the professional care of George McClellan of Philadelphia, who has kindly furnished me with some notes. I shall simply give an outline sketch of the case, describing particularly her epileptoid attack. For several weeks, during the absence of McClellan from the city, she was attended by M. O'Hara, and with him I saw her frequently in consultation.

Her face became flushed, her limbs and body rigid. The head and body were thrown backward to a moderate extent. Next, the shoulders were drawn upward, the head appearing to be sunk between them; the arms were found to be rigidly extended at her sides, the wrists partly flexed, and the fingers clenched; the legs also were spasmodically extended, the thighs drawn together, and the feet in the equino-varus or hysterical club-foot position. Phenomena like those described above as visceral spasm now were observed. The chest, and even the abdomen, were lifted up and down rapidly, and the respiration became quick, irregular, and apparently very difficult. Consciousness seemed to be impaired, but not absolutely lost. The symptoms just described took about one minute for their exhibition. Muscular relaxation now occurred, and an interval of calm, lasting about two minutes, followed, during which the patient spoke, answering one or two questions addressed to her. After the brief period of repose, however, another phase of the attack came on. In this the heaving movements of the body and what appeared to be intense respiratory spasms were the chief features. This portion of the attack endured scarcely a minute; the patient came to quickly, and was able to converse. In general, her attacks were of a similar character.

The drugs used included bromides, iodides, strychnia, chloride of sodium and gold, zinc salts, iron, etc. etc.; her condition vacillating, sometimes better, sometimes worse. She was finally placed in bed by McClellan, and an extension apparatus was employed, under which treatment, in a little more than one year from the time she was first attacked with spasm, she recovered.

The permanent or intervallary symptoms of hystero-epilepsy are in the main the phenomena which have been described when speaking of the prodromes of this affection. They are, indeed, the whole train of symptoms—the mental or psychical disorders, the motor, sensory, reflex, vaso-motor, and isolated phenomena—which have been described under special heads when considering the general symptomatology of hysteria. The full-fledged case of hystero-epilepsy is hysteria with a full array of special permanent hysterical manifestations, and the great paroxysm super-added. Certain phenomena are, however, more prominent and of much more frequent occurrence. Among these are paralysis or paresis, either of the unilateral or paraplegic variety; hemianæsthesia, including anæsthesia of all the senses; and contractures, particularly in the lower extremities.

DURATION AND COURSE.—The duration and course of hystero-epilepsy are very uncertain; most cases last many years. In a few instances the hystero-epileptic attacks are all from which the patient suffers; even in the cases of long duration the general health does not appear to become greatly impaired.

DIAGNOSIS.—To arrive at a correct diagnosis between hystero-epilepsy and epilepsy is sometimes very difficult. The fact that the patient is a male does not decide for epilepsy. In making this diagnosis close attention should be given to—1, The history and the causes of the disease; 2, the physical and mental condition of the patient; 3, above all, the phenomena of the spasmodic attacks.

In hystero-epilepsy a careful study of the history of the case will often

elicit a moral cause. The patients rarely injure themselves seriously by falling, whereas in true epilepsy they often suffer from severe injuries. The mental and physical health of a person suffering from hystero-epilepsy differs widely from that of the true epileptic. In hystero-epilepsy the number of attacks has little or no apparent influence on the patient's mental or physical condition. Little or no deterioration of the mind occurs. The memory is not much impaired. Hystero-epileptics are usually well nourished and frequently of good physique. This is not the case in true epilepsy; the number of attacks has a decided effect on the patient's mental condition. The demented appearance of the old epileptic is well known, whereas in the hystero-epileptic nothing in physiognomy or carriage indicates that the patient has been suffering from any disease. It cannot be said that all epileptics have no mental power, but some deterioration of the mind usually occurs, and becomes well marked as the case progresses.

The paroxysms in epilepsy are very well marked, especially if it is epilepsy of the grave form. They are often ushered in with a scream. The patient suddenly falls, and at times is severely injured. The convulsion is generally violent, rapidly alternating from clonic to tonic spasm, without special phases or periods. Complete and profound loss of consciousness, with great distortion of face and eyes, is present. The tongue is frequently bitten. After the attack the patient passes into a deep stupor. In hystero-epilepsy usually the seizure does not begin with a scream or sudden fall, the convulsion has periods and phases, and the tongue is not bitten.

It is said that in hystero-epilepsy there is no loss of consciousness, but this is not strictly true. This point is the most difficult one for physicians to clear up in arriving at a diagnosis, as in many textbooks complete loss of consciousness is laid down as the strongest evidence of epilepsy. Loss of consciousness does occur in hystero-epilepsy, particularly in certain varieties. Richer says that the loss of consciousness is complete during the entire epileptoid period in a case of the regular type. To decide as to consciousness or unconsciousness is not as easy as might be supposed. Varying degrees of consciousness may be present. At times in hystero-epileptic attacks the patient may respond to some external influences and not to others. Consciousness is perverted or obtunded often, and it is hard to decide whether the patient is positively and entirely unconscious of her surroundings. In epilepsy the loss of consciousness is profound and easily determined. In regard to the distortion of the face and eyes, this sign is usually absent in hystero-epilepsy, as in the German Hospital case, in which the patient had a series of violent seizures lasting two hours, with marked opisthotonos, yet the facial expression remained calm and serene throughout.

In hystero-epilepsy the attacks are rarely single; usually they are repeated, constituting the hystero-epileptic status. They are more frequently repeated than in epilepsy, although it is of course well known that there is an epileptic status terrible in character. In a series of hystero-epileptic attacks usually the seizures come on in rapid succession, the interval being brief. These series are apt to last for hours or days. The attacks that compose a series in hystero-epilepsy vary in duration and in violence. At first they are of violent character; toward the end

the seizures may gain in extent, but they are likely to lose in intensity.

Charcot and Bourneville make a strong diagnostic point between hystero-epilepsy and true epilepsy of the fact that in epilepsy there is a peculiar rise of temperature during the convulsion, even to 104° F., whereas in hystero-epilepsy the temperature is nearly or quite normal.

Arrest of attacks by ovarian compression in females, and by nerve compression, nitrite of amyl, and the application of electric currents, can be brought about in hystero-epilepsy, and not in epilepsy. A study of the effect of bromides may assist in arriving at a diagnosis. The action of bromides, drugs which are often used in both affections, favors the opinion that the two diseases are distinct. Bromides, according to Charcot and Richer, so effective in epilepsy, are without effect in hystero-epilepsy. Dujardin-Beaumetz, however, on the other hand, declares that "who says hysteria says bromides," and also that at the present time there is not an hysterical patient but has taken bromides, the bromide of potassium being most frequently used. The truth is, that bromides may be useful for temporary purposes, for certain phases and symptoms of the disease, but produce no radical permanent improvement in the disease hystero-epilepsy.

D. Webster Prentiss,¹ in reporting a case, gives some good points of distinction between real and hysterical tetanus, which is practically hystero-epilepsy. In his case, which was hysterical, the attack was ushered in by noise in the ears, deafness, and blindness, whereas in true tetanus and strychnia-poisoning the senses are preternaturally acute. There was unconsciousness during the paroxysm, which does not occur except just before death in the other affections. The eyes were closed during the spasms; they stare wildly open in the other diseases. The patient had long, uninterrupted sleep at night; in true tetanus no such relief comes until convalescence.

FIG. 25.

The figure is a representation of the opisthotonos of tetanus.² It is the sketch of a soldier, struck with opisthotonos after having been

¹ *American Journal of the Medical Sciences*, 1879.

² From Sir Charles Bell's *Anatomy and Physiology of Expression as connected with the Fine Arts*.

wounded in the head; and in connection with it I will briefly call attention to the points of differential diagnosis as given by Richer, and which have been confirmed by my own observations. In the opisthotonos of tetanus the contraction of the face and the peculiar grin are distinguishing points, and are well represented in Bell's sketch. In the hysterical arched position, while the jaws may be strongly forced together, the features are most often without expression. The contracture of the face and the distortion of the features will be met with more often in the other varieties of contortion. The curvature of the trunk differs but little in the two cases, but the abdominal depression observed in the sketch of Bell is far removed from the tympanitic appearance present in the majority of hystero-epileptics. In the tetanic cases the patient rests only on the heels, while in the hysterical cases the knees are slightly flexed, and the patients are usually supported on the bed by the soles of the feet.

Hystero-epileptics are often suspected of simulation. Richer refers to many facts which seem to throw out conclusively the idea of simulation. Among these are the results obtained by æsthesiogenic agents, the experiments in hypnotism, where many of the results produced could not be simulated. Some English authors—and among them notably the physiologist Carpenter—have endeavored to find the explanation of the results obtained by the æsthesiogenic agents in a special action of the moral on the physical nature which they designate expectant attention. While the reality of the action of expectant attention in certain cases will not be denied, it cannot be invoked to explain satisfactorily all the phenomena. The patients are not aware of the results sought; which, indeed, in some cases, are contrary to the expectations of the observer himself.

PROGNOSIS.—A few cases of hystero-epilepsy get well, either with or without treatment, in a short time. Some cases, which in addition to the grave attack have had in the intervals the other striking symptoms of major hysteria, such as hemianæsthesia and contractures, get well only after many months or years; some never recover, although, as a rule, they do not die from anything directly connected with the disease, but from some accident or more commonly from some intercurrent disorder. Cases supposed to be cured often relapse. The patient may be apparently well for months, or even years, when under some exciting cause the old disorder is again aroused. On the whole, the prognosis is more serious the longer the case has endured. Family history and environment have much to do with determining the prognosis.

TREATMENT.—In considering the treatment of hystero-epilepsy I will, in the main, confine my attention to a discussion of the methods of managing and treating the convulsive seizures. With reference to the numerous special phenomena of this disease, the directions given and the suggestions made in the general article on Hysteria will be equally applicable in this connection.

Ruault¹ has recently recommended compression of a superficial nerve-trunk in order to terminate an attack of hysteria or hystero-epilepsy. The face being always accessible, he prefers making pressure on the infraorbital nerves as they emerge from their foramina, but he has also

¹ *La France médicale*, vol. lxxxvi., p. 885.

compressed the ulnar nerve behind the inner condyle of the humerus. In a brief note to the Philadelphia Neurological Society, made Feb. 23, 1884, I called attention to the value of strong nerve-pressure for the relief of hysterical contracture, and can confirm from several successes Ruault's recommendation for the employment of the same measure to avert convulsive attacks.

Thiery¹ of the Saint Pierre Hospital, Brussels, arrests paroxysms by what he calls torsion of the abdominal walls. He grasps in his hands the walls of the abdomen and imparts to them a certain kind of torsion, which he gradually increases. This treatment is practically the same as the deep ovarian pressure of Charcot. This compression of the ovary on the side of the seat of the lesion ordinarily will arrest immediately the convulsions. The patient is extended horizontally, and the physician plunges the closed fist into the iliac fossa, often using great force to overcome the muscular resistance. Poiner has invented an apparatus called a compressor of the ovaries, which can sometimes be used with advantage.

Nitrate of amyl is undoubtedly of value in averting grave hysterical attacks—convulsions, trance, ecstasy, pseudo-coma, mania, etc. It is frequently used with marked success. Its action was studied on a vast scale at La Salpêtrière. The convulsions usually stop almost immediately after one, two, or three inhalations. It is to be preferred to inhalations of chloroform or ether.

Nitro-glycerin can be used in the treatment of the hystero-epileptoid convulsions. Notes of a very interesting case of hystero-epilepsy in which this remedy was successfully employed have been furnished me by David D. Stewart of Philadelphia. The case was one of hystero-epilepsy with combined crises. Amyl nitrate on several occasions broke the convulsive attack, but the patient did not completely regain consciousness. Stewart was called in during an attack, and found that the patient had been unconscious for an hour and a quarter. He gave her hypodermically three minims of a 1 per cent. solution of nitro-glycerin, and another injection after an interval of about eight minutes. She became conscious within one minute after the second injection. After this she had two seizures, both of which occurred on the same day, and yielded with remarkable promptness to a few minims of nitro-glycerin given by the mouth. She was put on three minims three times a day of this drug, the dose being gradually increased. Sufficient time has not elapsed to report as to the effect of the drug given during the intervals.

Strong faradic currents, applied with metallic electrodes to the soles of the feet or to the spine, are occasionally efficacious. The galvanic current to the head has been extensively employed in the service of Charcot to arrest hysterical and hystero-epileptic attacks of the grave variety. One electrode is applied to the forehead, the other to any convenient place upon the body, as the leg, the ovarian region, or the spine. The current is applied continuously for several minutes, or voltaic alternations are made. This method has been used with success in a few instances, but should never be resorted to by a physician uncertain of his diagnosis or one practically unfamiliar with the powers and properties of the electrical current.

¹ *Medical and Surgical Reporter*, Oct. 7, 1876.

The question of oöphorectomy for the relief of hystero-epilepsy is one of increasing importance in these days of major surgery. At the meeting of the American Neurological Association (June, 1884) G. L. Walton read a paper¹ in which he concludes that hysteria is sometimes set up by ovarian irritation, and can be relieved by removing the offending organ. He cited a single case. Carsten² concludes that it is criminal neglect not to perform Battey's operation in cases which fail to be benefited by other treatment. In the discussion which followed the reading of this paper the subject was well traversed by Spitzka of New York, Putnam of Boston, Putnam-Jacobi of New York, and others. Spitzka referred to one case of Israel's of Breslau, in which a patient was cured of hystero-epilepsy by a sham operation—a superficial incision in the parietes of the abdomen. Under the title of castration in hysteria the *Lancet*³ tells of an hysterical patient who had suffered for years from obstinate vomiting and severe ovarian pain. She became extremely weak, and finally consented to spaying as the only hope. The operation—performed under chloroform with antiseptic precautions—was a mockery, the skin only being incised; she was, however, perfectly cured of her hysterical symptoms.

In two clinical lectures published in the *Philadelphia Medical Times*⁴ I have given the histories of two cases of hystero-epilepsy in which oöphorectomy was resorted to for hystero-epilepsy. In the first of these cases, in which clitoridectomy was also performed, nymphomania, which was a distressing symptom, was benefited, but even this was not completely cured. The following is the patient's own statement: "Since the removal of the ovaries I have been able to control the desire when awake, but at times in my sleep I can feel something like an orgasm taking place. My experience leads me to say that my cure (?) is not due to the absence of the ovaries; there is no diminution of the sexual feeling. There would be as much excitement of the parts if the clitoris were still there. If my will gave way, I would be as bad as ever." Her general mental and nervous condition is much the same as before the operations. She is still dominated by morbid ideas, still unable to take up any vocation which demands persistence, and still the frequent subject of hystero-epileptic seizures.

The second of these cases was a young girl about seventeen years old who had never menstruated. She had had epileptic or hystero-epileptic seizures for several years. An operation was performed in which the ovaries and Fallopian tubes were removed. Twelve days after the operation, from which she made a good recovery, she had four convulsive seizures. She had several attacks subsequently, and then for a considerable period was exempt. She had, however, acute inflammatory rheumatism, with endocarditis and valvular trouble. About seven months after the operation she had several severe convulsions with loss of consciousness, and died about a year after the operation, having had many severe seizures during the last few weeks of her life.

There is no warrant either in experience or in a study of the subject for spaying hysterical girls who have never menstruated. In a case

¹ "A Contribution to the Study of Hysteria as Bearing on the Question of Oöphorectomy."

² Quoted by Walton from *American Journal of Obstetrics*, March, 1883.

³ Vol. ii. p. 588.

⁴ April 18 and May 30, 1885.

diagnosed as hysterical rhythmical chorea removal of the ovaries was advised by a distinguished specialist. The girl's trouble came on at about the age of thirteen years. She had never menstruated properly, although on one occasion, after several weeks of electric treatment, she had a slight show for a few days. It was proposed to remove the ovaries in this case on some general principle of given hysterical trouble; the ovaries must go. In this case, as in the last, it would have been far better to have put in a good pair of ovaries, or to have developed these rudimentary organs into health and activity.

With reference to oöphorectomy for hystero-epilepsy or any form of grave hysteria it may be concluded—1, It is only rarely justifiable; 2, it is not justifiable in the case of girls who have not menstruated; 3, when disease of the ovaries can be clearly made out by local objective signs, it is sometimes justifiable; 4, it is justifiable in some cases with violent nymphomania; 5, the operation is frequently performed without due consideration, and the statistics of the operation are peculiarly unreliable.

When we come to consider the treatment of the disease hystero-epilepsy, the practical importance of the distinction between this affection and true epilepsy becomes apparent. Cures of hystero-epilepsy are not rare. The original cases here reported have all apparently recovered. Grave hysteria is sometimes cured spontaneously, either by gradual disappearance with the progress of age, or suddenly because of some violent impression or under the influence of unknown causes. One of the worst cases in the service of Charcot has shown a gradual diminution of the hystero-epileptic manifestations with the advance of age. In another case under the influence of strong moral impressions the disease disappeared at a stroke. The affection, however, should not be abandoned to nature, as treatment is often of value.

The hydrotherapeutic method of treatment has been found of the greatest service. Hydrotherapy must be methodically employed by experienced hands. A number of cases cited by Richer were cured at hydrotherapeutic institutions. Limited success has followed the use of metallo-therapy. Besides metallic plates, the same results may be obtained with other physical agents, to which have been given the name of *æsthesiogenic agents*. Among these are feeble electric currents, vibrations of a tuning-fork, static electricity, etc.

Static electricity has a position of undoubted importance in the treatment of hystero-epilepsy in some of its phases. Those who have walked in the wards and visited the laboratories of Salpêtrière will recall the enormous insulated stools to which are brought troops of hystero-epileptic patients, who, to save time, are given a vigorous simultaneous charge of electricity. Even this wholesale plan of treatment is sometimes markedly efficacious. Vigoroux recommends static electricity as an *æsthesiogenic agent*, and regards it as the most valuable of all agents of this character.

Those drugs should be resorted to which have a tonic influence on the nervous system. Potassium bromide, as has already been indicated, is not efficacious. More is to be hoped from tonics and anti-spasmodics, such as valerian, iron, salts of silver, zinc, copper, sodium, and gold chlorides, etc. Good hygienic influences, moral, mental, and physical, are of the utmost importance.

CATALEPSY.

BY CHARLES K. MILLS, M.D.

DEFINITION.—Catalepsy is a functional nervous disease characterized by conditions of perverted consciousness, diminished sensibility, and especially by muscular rigidity or immobility, which is independent of the will, and in consequence of which the whole body, the limbs, or the parts affected remain in any position or attitude in which they may be placed.

Catalepsy sometimes, but not frequently, occurs as an independent disease; that is, the cataleptic seizure is the only abnormal phenomena exhibited by the patient. It is sometimes present, although also rarely, in organic disease of the nervous system. It has been noted, for instance, as occurring in the course of cases of cerebral hemorrhage, softening of the brain, abscess, tumor, and tubercular meningitis. One case is referred to by C. Handfield Jones in which it seemed to be due to intracranial epithelioma. As commonly seen, it is a complication, or perhaps, more properly speaking, a form of hysteria—hystero-catalepsy.

SYNONYMS.—Some of the many synonyms which have been used for catalepsy are *Catochus*, *Morbus attonitus*, *Stupor vigilans*, *Synochus*, *Eclipsis*, and *Hysteria cataleptica*. Trance and ecstasy are discussed sometimes as synonymous with catalepsy, but they will be considered as separate affections, as they have certain distinctive features. Catalepsy, trance, ecstasy, hystero-epilepsy, and other severe nervous disturbances may, however, all appear in the same patient at different times or at different stages of the same seizure.

With reference to the term *catochus* (*κατοχή*, from *κατεχω*, I take possession of), which has been used as synonymous with catalepsy, Laycock¹ points out what he considers to be the proper use of this word, differentiating two cataleptic conditions, which he designates as the tetanic and the paralytic states. *Catochus* is the tetanic form, in which the trunk and limbs are rigidly extended and consciousness is abolished. Catalepsy proper is Laycock's paralytic form, although the term paralytic, as here applied, is by no means happy. It is the form characterized by the peculiar and striking symptom known as waxen flexibility (*flexibilitas cerea*)—a condition in which the limbs or parts are passive and are capable of being moulded like wax or lead pipe. Rosenthal would not consider any case as one of genuine catalepsy if this waxen flexibility was absent. I do not think that this rigorous criterion should always be imposed,

¹ *A Treatise on the Nervous Diseases of Women*, by Thomas Laycock, M.D., London, 1840.

although it might perhaps be better to apply the term cataleptoid to all cases which do not present true wax-like flexibility. The distinction sometimes made between catalepsia vera, or true catalepsy, and catalepsia spuria, or false catalepsy, is practically that indicated between Laycock's two forms. According to Charcot and Richer,¹ the *flexibilitas cerea* is not present in the cataleptic state of hypnotism.

HISTORY.—The word catalepsy was used by Greek writers in its etymological signification of a seizure or surprise. Hippocrates described catalepsy; Galen, Aëtius, Rondeletius, and Fernelius have all related cases; Aëtius has left an accurate description of both catochus and catalepsy. In 1683, Laurence Bellini published a quarto volume on various subjects, one of which was catalepsy. From time to time interesting cases of catalepsy have been reported by medical writers. One of the best is that recorded by John Jebb in 1782, and quoted by Chambers in *Reynolds's System of Medicine*. The researches in hypnotism during the present century, and particularly those of Heidenhain and of Charcot and Richer, have thrown new light on many cataleptic phenomena.

ETIOLOGY.—In catalepsy, as in hysteria, insanity, and many neuroses, inheritance frequently plays a predisposing part. Eulenburg places it in the large group of diseased conditions designated by Griesinger constitutional neuropathies. The cataleptic of one generation may be the descendant of the insane, the epileptic, the syphilitic, or the alcoholized of a former. Catalepsy is particularly likely to occur in families which have a history of insanity or drunkenness. Of the cases detailed or alluded to in this paper, more than a majority had a clear neurotic history. Catalepsy, like hysteria, occurs with some frequency among the tuberculous.

Age plays some part in the development of catalepsy. It is of most frequent occurrence between the ages of fifteen and thirty, but has been observed at all ages. It is of unusual occurrence in very early childhood, but A. Jacoby,² Clinical Professor of the Diseases of Children in the College of Physicians and Surgeons in New York, reports a case of well-marked catalepsy in a child three years old. This patient, a girl, was admitted to the Mt. Sinai Hospital, New York, in September, 1879. She had whooping cough and some symptoms of typhoid fever. After she had been in the hospital three weeks choreic twitchings of the eyes and eyelids, with divergent strabismus, were observed. Examining her, it was found that she was cataleptic; her arms and legs would remain in any position in which they were placed; she would drop the uplifted arms slowly when commanded; sensibility to contact, pain, and temperature were entirely lost, and the skin and patellar reflexes were diminished. Her appetite was ravenous, and urine was passed in large quantities. Other phenomena and details of cataleptic symptoms, which continued for about a month, are recorded by Jacoby. The child recovered, but remained weak and anæmic for a long time.

Monti³ records eleven cases of catalepsy met with in children, male and female in about equal numbers, of from five to fifteen years, the average age being nine years. Eulenburg speaks of catalepsy at five

¹ *Journal of Mental and Nervous Diseases*, Jan., 1883.

² *American Journal of Medical Science*, N. S. lxxxix., 1885, p. 450.

³ *Gerhardt's Handb. d. Kinderk.*, vol. v., L. P., 186 *et seq.*, quoted by Jacobi.

years of age, and quotes Schwartz, who noticed in a boy seven years old, in consequence of rough treatment, first a choreic condition, which later passed into catalepsy. Lloyd's case, to be detailed later, also studied by myself at the University Hospital, was in a boy eight years old. B. L. Hovey¹ of Rochester, New York, reports an interesting case of catalepsy in a boy eight years old.

C. E. de Schweinitz of Philadelphia, Ophthalmic Surgeon to the Children's Hospital and Prosecutor of Anatomy at the University of Pennsylvania, has kindly put into my hands the unpublished notes of a highly interesting case of catalepsy or automatism at command, or of both, in a child two and a half years old. I will give this case in full, chiefly in the language of De Schweinitz, because it is, so far as I know, the youngest case on record. Some of the tests which were applied in this case are among the most useful which can be resorted to in determining how far the phenomena presented are genuine or induced, simulated, or imitated:

The patient was a girl aged two and a half years, who had recently recovered from an attack of diphtheritic conjunctivitis. During the period of her convalescence the attending nurse called attention to the unusual position assumed by the child while sleeping—viz. a lateral decubitus, the head raised a short distance from the pillow, and the forearm slightly elevated and stretched out from the body, the muscles at the same time exhibiting marked tremulousness. A series of trials readily demonstrated that the child when awake could be placed in any position compatible with her muscular power, and that she could thus remain until released. She was placed, for instance, in the sitting posture, the arm brought at right angles to the body, the forearm at right angles to the arm, and the hand at right angles to the forearm, both legs raised from the bed, and the head bent backward. This position, a most uncomfortable and difficult one to preserve, would be maintained until the little subject dropped from sheer exhaustion. Flexion and extension of each separate finger were easily produced, and the fingers remained until replaced in the positions in which they had been fixed. At the beginning the child's mind was sluggish, although she asked for food and made known her various wants. How far she appreciated surrounding objects could not be accurately ascertained, inasmuch as the previous disease of her eyes had left her with a central corneal macula on each side, rendering her almost sightless in one eye and with but indifferent object-perception in the other. Voluntary motion was preserved, and she sat up, turned, and moved whenever she pleased, but most often when at rest at this stage maintained somewhat of the position before described which during sleep first attracted attention to this condition.

In conjunction with Morris Lewis an examination of the cutaneous sensibility and reflexes was made, which showed diminished sensibility in the legs and thighs, but not higher up, where the pricks of the instrument were quickly appreciated. Her knee-jerk was apparently absent on the right side and present on the left; but this test, always most unsatisfactory in children, yielded no certain evidence and constantly gave contradictory results. Scratching the skin of the soles of the feet, legs, thighs, and abdomen with a pointed instrument was fol-

¹ *The Hospital Gazette*, 1879, vi. p. 19.

lowed by marked reflex movements. Electro-muscular contractility was everywhere preserved. The child at this time was feeble and anæmic, but her appetite was good—not depraved nor voracious; the tongue was clean, the bowels regular. The urine was of a light amber color, specific gravity 1020, free from albumen and sugar.

As the nutrition of the child improved, it was found that the curious positions could be produced by word of command as well as by manipulation. In short, within six weeks after the first manifestations of this disorder, as a usual thing the little patient ate, slept, and played as a normal child should do, but could at any time be thrown into this cataleptoid state. Her one dominant idea apparently was to maintain the position in which she had been placed. She was often turned into some constrained posture, and all attendants absented themselves from the room and left her to her own devices; but no attempt on her part was made to in any way change her attitude. If at dinner-time a bowl of broth was placed before the patient, she would begin to eat with great relish, but if the spoon was taken away and her hands raised over her head, they would so remain, the child making no effort to return to her meal, although the bowl stood before her and all watchers again retired from the room. This experiment was suggested by H. C. Wood, who examined the child with me. To show how completely her consciousness was occupied with one idea of maintaining any position in which she had been placed, the following additional experiments may be quoted: If she was put into a sitting position, as in the act of supplication, with her hands folded and arms extended, and then given a sudden push sufficient to overthrow her equilibrium, the arms would be quickly and intuitively thrown out to protect her from the impending fall, but, the fall accomplished, they would as quickly be returned to their former position. If a heated silver spoon was gradually brought in contact with her extended hand, an expression of pain would pass across the child's face, perhaps a cry escape her, and the injured member be rapidly withdrawn, but again almost immediately returned to its original place. It seemed as if the idea of fixity in a certain position which occupied the child's mind was suddenly disturbed by another outside impression, but, being dominant, it quickly drove away the intruder and the former state was restored. At this time the phenomena noted were somewhat in accord with those induced by the mesmeric process, inasmuch as the consciousness seemed largely given up to the one impression operating at that time—*i. e.* the maintenance of certain fixed positions. Unlike this condition, however, the readiness to receive new impressions, and the complete abeyance of those senses not operating was wanting, for, as seen above, the new impression only for a moment disturbed the child's one idea, to which she quickly returned; nor was there any true absence of sensibility, as was evidenced by the result from touching her with a heated spoon.

As time wore on, a new phase of this condition became evident. The induced manifestations seemed to act the part of some amusement to the child, and the complete absence of volition which had been an early characteristic phenomenon was not now so marked a feature. Thus, if, after the experimenter had for a time moulded and twisted the child into various shapes, he would suddenly leave the room, the little subject

would cry lustily, as a child does when suddenly deprived of its play-things, although, curiously enough, no matter how hard she cried, she would not release herself from the last position in which she had been left. Often during any series of observations that were being made it was noted that a faintly-amused look played about her lips, which speedily gave way to a fit of crying when the performance stopped. The hand which, when formerly placed in any position, remained a perfectly motionless and passive object, was now seen slightly to change its place, move the fingers, or the like—an observation first made by A. K. Meigs while examining the patient. The house-physician, Nathan P. Grimm, took great care and interest in observing the case.

De Schweinitz, in reporting the case, briefly discusses the probable cause of the phenomena exhibited. He discards the views that either fear of the experimenter, such as is shown by a trained animal, or the partial blindness of the child, was responsible for the manifestations. He believes that a direct relation existed between the phenomena and the state of the child's nutrition. The more run down her system was, the more nearly did the nervous phenomena resemble those of true catalepsy. Evidently, her symptoms were partly cataleptic and partly phenomena of automatism at command, similar to those which have been observed in hypnotic experiments, and which will be alluded to later.

Catalepsy is of more frequency in the female than in the male sex, but the statistics are not sufficient to give any exact ratio.

The periods of puberty and early menstruation and of pregnancy furnish the most favorable opportunities for the development of cataleptoid seizures in predisposed individuals. In 3 of 10 cases observed by Landouzy catalepsy appeared to be developed in consequence of the sudden suppression of menstruation; in a fourth it occurred in a young girl after a dysmenorrhœa with chronic phlegmasia of the genitals. Masturbation is sometimes mentioned as a cause, particularly in boys.

Reflex irritation undoubtedly often acts as an exciting cause of catalepsy. Preputial irritation, relieved in part by circumcision, was present in the case of Lloyd, and has been noted by others. Handfield Jones mentions a case, recorded by Austen in his work on *General Paralysis*, in which the cataleptic seizure was, to all appearances, due to fecal accumulations. The attack disappeared promptly after an enema had thoroughly operated.

Briquet believed that catalepsy, when it did not follow upon organic disease, was ordinarily the result of moral causes, such as vivid and strong emotions—fear, chagrin, indigestion, anger, or profound and prolonged meditation. He refers to the able and curious thesis of Favrot,¹ who states that in twenty cases in which the causes of the malady were indicated it had been always the result of a moral affection. A magistrate insulted at his tribunal, seized with indignation, is suddenly taken with catalepsy, etc. According to Puel, its causes are always depressing moral affections, as chagrin, hatred, jealousy, and terror at bad treatment. Unrequited love is set down as a cause, but what has not unrequited love produced? Jones mentions a case which occurred in a man sixty years old on the sudden death of his wife.

¹ "De la Catalepsie"—Mémoire couronné par l'Académie de Médecine, *Mémoires de l'Académie de Médecine*, Paris, 1856, t. xx. p. 409, A. 526.

Cullen believed that catalepsy was always a simulated disease; he preferred, therefore, to place it as a species of apoplexy. Temporary catalepsy may, according to Rosenthal, be produced in hysterical patients by covering their eyes with their hands or a cloth. Malaria has been charged with the production of catalepsy, and apparently properly. Traumatism is another of its well-authenticated causes. Blows upon the head have been particularly recorded as having an etiological relation to this disorder.

Partial catalepsy has been observed after typhoid fever with severe cerebral symptoms, and also associated with meningitis and intermittent fever. Mancini¹ relates a case of cerebral rheumatism complicated or causing catalepsy. A blacksmith, aged thirty-three, had nearly recovered from a rheumatic attack when he became melancholic, complaining also of severe headache. When admitted to the hospital he was found to be imperfectly nourished. He lay on his back, his face without expression, speechless, motionless, pupils insensible to the light, smell impaired, sensation of heat and pain and reflexes absent, galvanic and faradic contractility increased, the rectum and bladder paralyzed. He presented the phenomena of waxen flexibility, the trunk and limbs remaining in whatever position was given them. Considering the previous attack of articular rheumatism and the sudden appearance of nervous disorder during the convalescence of this disease, Mancini believed that the case was probably one of cerebral rheumatism. The man recovered under diaphoretics and counter-irritation.

Among the important causes of catalepsy bad nutrition may undoubtedly be placed. In the case of De Schweinitz the cataleptoid phenomena rapidly improved, and eventually disappeared as the child's general health was restored by tonics and good diet. Hovey's case was insufficiently clad and badly fed. One of Laségue's cases, quoted by Handfield Jones, died of gradual marasmus, another of pulmonary phthisis. Attacks of catalepsy have sometimes resulted from a combination of excitement, fatigue, and want of food. They occur also in diseases or conditions like phthisis, anæmia, and chlorosis, affections which practically gives us the same cause—namely, bad nutrition. In these cases the nervous system, like other parts of the body, takes part in the general exhaustion.

Rosenthal refers to the production of symptoms of temporary catalepsy by the administration of narcotics and the inhalation of ether and chloroform. In a somewhat ancient American medical periodical² Charles D. Meigs of Philadelphia gives an interesting account of a case of catalepsy produced by opium in a man twenty-seven years of age. The man had taken laudanum. His arms when in a stuporous condition remained in any posture in which they happened to be left; his head was lifted off the pillow, and so remained. "If he were made of wax," says Meigs, "he could not more steadily preserve any given attitude." The patient recovered under purging, emetics, and bleeding. Darwin, quoted by Meigs, mentions a case of catalepsy which occurred after the patient had taken mercury. He recovered in a few weeks.

That imitation is an exciting cause of catalepsy has been shown by the

¹ *Lo Sperimentale*, March, 1878.

² *The North American Medical and Surgical Journal*, vol. i. p. 74, 1826.

often-told story of epidemic hysteria, but more especially by accounts given of certain peculiar endemics of catalepsy. Handfield Jones¹ gives an account of an endemic which prevailed at Billingham near Wurzburg: "The population consists of peasants who are well off, but who intermarry very much, and are small and deformed. The affected individuals constitute half of the number, males as well as females. They are called there the stiff ones (*starren*). A chill is commonly said to be the exciting cause of the attacks. The patients are suddenly seized by a peculiar sensation in their limbs, upon which all their muscles become tense, their countenances deadly pale; they retain the posture which they first assume; their fingers are bent and quiver slightly, and the eyeballs in the same way, the visual axis converging; their intellects and senses are normal, but their speech consists only of broken sounds. The attack ceases in from one to five minutes, and the body becomes warm."

SYMPTOMATOLOGY.—The cataleptic seizure, when it is not the result of some hypnotizing procedure, usually takes place in the following manner: The patient usually, after some patent exciting cause, suddenly ceases whatever she may chance to be doing, becoming rigid and immobile in the last position which she had been in before the attack ensued. "She remains," says Rosenthal, "as if petrified by the head of Medusa." The features are composed, the eyes usually directed forward. She is pale; breathing, pulsation, and temperature are usually somewhat reduced. At first the limbs may be found to offer some resistance; soon, however, and sometimes from the beginning, they can be moulded like wax into any possible position, where they will remain until again changed by external agency.

Attacks of catalepsy, as a rule, come on suddenly, without special warning; sometimes, however, special phenomena, which may be compared to epileptic aura, may precede the attack. Thus, Rosenthal speaks of two cases that were ushered in, and also bowed out, by hiccough. The attacks may terminate as suddenly as they begin, but sometimes the patients come out of the state gradually. They are quite likely to appear dazed and stupid when emerging.

Perverted consciousness is another marked symptom of catalepsy. According to some authors, the loss of consciousness is absolute, and upon this symptom they base their diagnosis from two or three other somewhat similar conditions. As I have already indicated in discussing the general subject of Hysteria, this question of consciousness or unconsciousness is not one to be decided in haste. In catalepsy, as in hysteropilepsy, the conditions as to consciousness may differ. What might be termed volitional consciousness is in true catalepsy certainly in abeyance. Flint² divides catalepsy, according to the condition as to consciousness, into three kinds—namely, complete, incomplete, and complicated. He, however, regards trance and day-mare as instances of incomplete catalepsy, in which the intellectual faculties are not entirely suspended and the senses are not materially affected, the patient being unable to move or speak, but conscious of all that is going on around him. He believes that such cases resemble more closely the cataleptic condition than they do that of ecstasy. In genuine catalepsy with waxen flexibility, analgesia, etc. there may be

¹ *Op. cit.*, quoted from *Schmidt's Jahrbuch*.

² *Buffalo Medical Journal*, xiii., 1857-58, p. 141.

greater or less depths of unconsciousness, but some degree of unconsciousness or of obtunded consciousness is necessary to the existence of true catalepsy.

Catalepsy presents well-marked disturbances of sensation, although these, like the conditions as to consciousness, differ somewhat in different cases. Anæsthesia in its different forms, and especially analgesia, are always present in some degree. Experiments without number have been tried on cataleptic patients, showing their insensibility to painful impressions: they have been pinched, pricked, pounded, burned with heated irons, and rubbed down with blocks of ice. Skoda reports a case in which general sensibility was abolished, but a lighted paper rotated rapidly before the eyes gave rise to tremors of the limbs, and strong odors induced slight movement, redness of the cheeks, lachrymation, acceleration of the pulse, and elevation of the temperature.

Hyperæsthesia, although rare, has been noted in a few isolated cases of catalepsy. Puel records a case in which, during the cataleptic paroxysm, the slightest touch or noise caused the patient to grind the teeth and cry out. In some cases sensibility to certain special impressions, as to a strong current of electricity, has been retained, while all others were abolished. In a case of hysterical catalepsy at the Philadelphia Hospital, when all other measures had failed an attack was aborted and evidence of pain produced by the application of a strong faradic current with metallic electrodes.

A marked change in the state of reflex irritability is another of the striking symptoms of true catalepsy. Varying conditions as to reflex irritability have been observed by different authors. So far as I am aware, few special observations have been made upon the tendon reflexes in catalepsy. In the case of De Schweinitz the knee-jerk was apparently absent on one side and present on the other, although the cataleptic symptoms were not unilateral.

The symptom known as *flexibilitas cerea*, or wax-like flexibility, to which I have referred under Synonyms, is, as has been stated, by some considered pathognomonic of this affection. While I do not hold to this view, I regard the symptom as the most important phenomenon of the disease. It is a symptom which from its very nature can be, up to a certain point, readily shammed, and when considering Diagnosis some methods of determining its genuineness will be given.

Careful observation as to the pulse, respiration, and temperature are lacking in the reported cases of catalepsy. According to Eulenburg,¹ "the respiration is generally of normal frequency, sometimes rather slow, more frequently of diminished or irregular intensity, so that lighter and deeper inspirations alternate. The pulse may also be slower, with slight excursion and diminished tension of the arteries. The temperature generally remains normal, but in certain cases is decidedly lowered." The lowering of temperature, and particularly the presence of extreme coldness of the surface, with exceedingly weak pulse and respiration, have doubtless always been present in the cases—a few, at least, authentic—in which catalepsy has been supposed to be death.

¹ *Op. cit.*

Hypnotic Catalepsy.

The investigations into the subject of hypnotism made in recent years have given to the profession a series of interesting phenomena which should be considered, at least briefly, under the symptomatology of catalepsy. In a general review of the subject of hypnotism¹ by me many of the facts observed and theories advanced by Braid, Heidenhain, Charcot, Richer, and others were examined. I will here recall those observations of Heidenhain² and of Charcot and Richer³ which relate to the production of a cataleptic or cataleptoid state, and to the phenomena which take place in this state.

The method of Heidenhain was similar to that employed by Braid. The latter, however, did not make use of passes. In the first place, the individual was made to gaze fixedly at a shining faceted glass button for some six or eight minutes, the visual axes being made to converge as much as possible. Heidenhain, like Braid, found the most advantageous direction of the visual axes to be that of upward convergence. According to Carpenter, in the fixation this upward convergence is very important; it suffices of itself in blind people or in the night to produce hypnosis. After the fixation of gaze had been continued for some six or eight minutes, the operator stroked over the face, without immediately touching the surface, from the forehead to the chest, after each pass bringing the hands, which were warm, around in an arc to the forehead again. He either allowed the eyelids to be closed or gently closed them. After ten or twelve passes he asked the person to open his eyes. When this occurred without hesitation or with only slight difficulty, he again made the person stare at the glass for some six minutes, and then repeated the passes, which often brought about the hypnotic state when the simple fixation did not succeed.

The symptoms of the hypnotic state were in the main those which have just been described as the symptoms of catalepsy—namely, diminution of consciousness, insensibility, increased reflex irritability, and fixity of the body or limbs in any position given.

In the slighter forms of hypnotism the subjects were able to remember what had occurred during their apparent sleep. In more fully-developed forms they had no remembrance of what had taken place, but by giving hints and leading questions of their various actions they were able to call them to mind. In the most complete forms of hypnotism no remembrance whatever was retained. It can nevertheless be proved that even during the most completely developed hypnosis sensory perceptions take place, but they are no longer converted into conscious ideas, and consequently are not retained by the memory; and this is undoubtedly because the hypnotized individuals have lost the power of directing their attention to their sensations.

A symptom of the hypnotic state in its most complete development was highly marked insensibility to pain. A pin could be run right into the hand, and only an indistinct feeling of contact was brought about. Imme-

³ *Études cliniques sur l'Hystero-épilepsie, ou Grande Hystérie*.

diately on awaking the full sense of pain was again present. The fact that the tactile sense and the sense of pain are distinct was corroborated.

Increased reflex irritability and tonic spasm of the voluntary muscles accompanied the hypnotic condition. Stroking the flexible right arm of a subject, it at once became stiff, since all the muscles were thrown into a state of reflex spasm. Reflex muscular contraction spread over the body when certain definite cutaneous surfaces were irritated. With slight increase of reflex irritability those muscles alone contracted which lay immediately under the area of the skin which had been stroked. Stroking the ball of the thumb caused adduction of the thumb. Stimulating the skin over the sterno-mastoid caused the head to assume the stiff-neck position. When the irritability was somewhat more increased, by a continuous irritation of a definite spot of skin neighboring and even distant groups of muscles could be set into activity. Heidenhain stroked continuously the ball of the left thumb of his brother, when the following muscle-groups were successively affected with spasm: left thumb, left hand, left forearm, left upper arm and shoulder, right shoulder and arm, right forearm, right hand, left leg, left thigh, right thigh, right leg, muscles of mastication, muscles of the neck.

From a study of such phenomena Heidenhain was inclined to consider that the hypnotic state was nothing more than artificially produced catalepsy.

The possibility of fixing any part of the body in any given position constituted an essential factor in the exhibition of Hansen. He made one of his subjects, for instance, sit before him in a chair, and adapted the hands to the seat so that his fingers grasped the edges. After hypnotizing him he stroked along his arms, and his fingers took convulsive hold of the edges of the seat. Placing himself in front of the subject, he bent forward; the subject did the same. He then walked noisily backward, and thereupon the subject followed him through the hall, carrying his chair with him like a snail its shell.

One of the observations of Richer was on the influence of light on catalepsy and hysterical lethargy. The patient was placed before a bright focus of light, as a Drummond or electric light, on which she was requested to fix her sight. In a short time, usually a few seconds or several minutes, sometimes instantaneously, she passed into the cataleptic state. She was as one fascinated—immobile, the wide-open eye fixed on the light, the conjunctiva injected and humid. Anæsthesia was complete. If the patient was hemianæsthetic, she became totally anæsthetic. She did not present contractures. Her limbs preserved the suppleness of the normal state or nearly this—sometimes being the seat of a certain stiffness; but they acquired the singular property of preserving the attitude which one gave them. One interesting peculiarity was the influence of gesture on physiognomy. The features reflected the expression of the gesture. A tragic attitude imprinted a severe air on the physiognomy; the brows contracted. If one brought the two hands to the mouth, as in the act of sending a kiss, a smile immediately appeared on the lips. It was an example of what Braid calls the phenomena of suggestion—of Heidenhain's imitation. The state of catalepsy endured as long as the agent which produced it—that is, as long as the light continued to impress the retina.

The characteristics of the two abnormal states—catalepsy and lethargy—into which hysterico-epileptics may be thrown were summarized by Richer as follows: (1) Cataleptic state: The eyes wide open; total and absolute anæsthesia; aptitude of the limbs and different parts of the body to preserve the situation in which they are placed; little or no muscular rigidity; impossibility of causing muscular contraction by mechanical excitation. (2) Lethargic state: The eyes wide open or half closed; persistent trembling of the upper eyelids; convulsion of the eyeballs; total and absolute anæsthesia; muscular hyperexcitability; the limbs, in a condition of resolution, do not preserve the situation given to them, except the provoked contracture impressed upon them.

In the experiments at Salpêtrière the hysterico-epileptics were sometimes plunged into the states of catalepsy and lethargy under the influence of sonorous vibrations instead of frights.

During the state of provoked hysterical catalepsy it was found that sight and hearing could be affected by various procedures. The eyes were fixed, and seemed not to see anything. If, however, an object was slightly oscillated in the axis of the visual rays at a little distance from the eyes, soon the gaze of the patient followed these movements. The eyes, and sometimes even the head, seemed to turn at the will of the operator. Hallucinations were produced. When the look was directed upward the expression became laughing; when downward, sombre. The cataleptic state might now cease completely. The patient walked, followed the object on which her gaze was fixed, and took attitudes in relation with the hallucination suggested. Music also caused her to assume positions related with the various sentiments suggested to her by the music. Sudden withdrawal of the object from before the eyes or of the sound from the range of hearing caused a return of the catalepsy. The cataleptic patient in whom the eye was in such a state as to perceive the movements of an experimenter placed in front of her reproduced these movements exactly. At the Philadelphia Hospital I have repeated most of the experiments of Heidenham and of Charcot and Richer.

Unilateral Catalepsy.

Hemi-catalepsy or unilateral catalepsy is sometimes observed, and has been studied both in hypnotic investigations and as a special nervous affection. Charcot and Richer found that hemi-catalepsy or lethargy may be produced on a patient, and that they may both exist simultaneously in the same subject. When, for instance, a patient was plunged into the cataleptic state under the influence of a bright light, shutting with the hand one of the eyes, the patient at once became lethargic on the same side only; the other side remained cataleptic. Heidenham and Gruetzner studied some remarkable phenomena, which they have recorded under the name of unilateral hypnosis, in which some surprising sensory disturbances occur. They also found, among other things, a striking disturbance in the process of accommodation and in the perception of colors in the eye of the cataleptic side. In a case of hysterico-epilepsy upon which I performed numerous hypnotic experiments which have been reported¹

¹ *Philadelphia Med. Times*, Nov. 19, 1881.

the patient nearly always presented unilateral cataleptic phenomena. These were present on the left side, the patient being subject to convulsions which were more marked on the right side, this being also much wasted.

I witnessed some curious unilateral cataleptoid phenomena in the case of a medical friend, who has made a note of his experience.¹ He says: "In the course of some experiments on table-tipping, which were conducted mainly to satisfy the curiosity of persons who had never seen anything of the kind, I became the subject of a very peculiar and marked hypnotic influence. The ordinary tricks of tipping, answering questions, guessing numbers, etc. had been performed with the table, during the greater part of which I had been one of the circle, when my right hand began to contract so as to form an arch, and was then lifted from the table. These movements were not volitional; I was unable to control them. While my hand was in this position one of the persons sitting at the table suddenly put his hand on my forehead, and I sank back in the chair, passing into a conscious but apparently powerless state, but only for a few moments. Later in the evening the hypnotic influence in the right hand was still more distinctly manifested. If allowed to remain a short time on the table, the fingers began to vibrate vertically and horizontally, the motion finally extending to the forearm and becoming so violent as to throw the hand about in a rapid and forcible manner. While thus affected I found it utterly impossible to sign my name. I would be able to form the first letter or so, and then most extraordinary gyrations would be made. In one instance I wrote very slowly, using all the muscular control at my command, and succeeded in writing the full name, but in a form wholly different from my ordinary signature."

My attention was called to these phenomena, and the experiments were repeated the next week in my presence, with like results. In addition, I succeeded in forcibly placing the affected arm in various positions—bent at right angles, the hand resting on the top of the head, etc.—from which positions he was unable to move it. He seemed to have lost the connection between volition and the motor impulse. The experiments were continued for several hours at each sitting, but owing to the depressed mental state which was produced for a short time, apparently by them, they have not been repeated.

Occasionally, cases of unilateral catalepsy associated with rotatory phenomena are met with, especially in hysterical children. In 1882, I studied in the nervous dispensary of the hospital of the University of Pennsylvania an interesting case with rotatory and unilateral cataleptoid symptoms. This case has been reported by James Hendrie Lloyd.² The patient was a boy eight years old. His paternal grandfather hanged himself. On the mother's side there was a history of tuberculosis. Two years before coming to the hospital he had had four attacks of spasms. For two weeks he had been having from twelve to twenty similar spasms daily; some of these were observed in the dispensary. "The boy's head was suddenly drawn upward and to the right to its extreme limits by the action chiefly of the sterno-cleido-mastoid muscle. The eyes turned also to the extreme right, with slight convulsive (clonic) action, and became

¹ *Polyclinic*, Sept. 15, 1883.

² *Philada. Med. Times*, vol. xii., June 17, 1882.

fixed in that position, with very wide dilatation of the pupils. In a second or two he began to rotate his whole body to the right, and turned completely around, perhaps ten or twelve times. On some occasions he had fallen down, his mother said, toward the end of the spell. If taken hold of and steadied—which required but little force by the physician—the rotation could be stopped, though the head and eyes remained drawn, and the boy's arms could be placed in any desired position. If now he was once more let loose, his body again rotated, while his arms were held in true cataleptoid rigidity. The whole duration of the attack was from one half to one minute. The boy was intelligent, and said he knew what was taking place about him while he was in the fit, though he gave no satisfactory evidence of such knowledge at the time. There was no history of headache or any disease. His ears were subsequently examined and found normal. He had taken worm medicine in abundance from the family physician without results. There were no psychical traits of importance to suggest foolish or wilful simulation. The only accident had been a fall from a wagon years previously. As the patient had an adherent prepuce, Wood advised circumcision, and took pains to explain the operation to the mother. This evidently made a great impression on the child's mind, which is worthy of notice in considering the case. The potassium bromide was continued. At the third visit, which had been appointed for the operation of circumcision, the mother reported the patient much better. The boy had been having great fear of the proposed operation, and now said that he thought he could control the spells. A psychical element was thus distinctly indicated, and its likeness to chorea major to some extent increased. It was thought best, however, instead of circumcision, to break up adhesions and retract the foreskin, which was done by J. William White. At the fourth visit, after ten days, a still greater improvement was noted."

Lloyd in reporting this case discusses the physiology of the condition, and refers to other cases in medical literature. According to Brown-Séquard, the great cause of rotation phenomena is a convulsive contraction in some of the muscles on one side of the body. Carpenter believes they are due to weakness of the sensori-motor apparatus of one side. Laycock holds that the cerebellum is involved. Lloyd likens the case to chorea major. He refers to cases reported by Radcliffe¹ and J. Andrew Crawford.²

At the Pennsylvania Training School for Feeble-minded Children at Elwyn is a little patient familiarly spoken of as the Dervish. I have examined this boy several times, and have frequently watched his performances. I. N. Kerlin, superintendent of the institution, has kindly furnished me with some notes of this case. The antecedents of the patient are unknown. He is about fifteen years of age, is of small stature and weight, a demi-microcephalic, epileptic, and mute idiot. His epilepsy, however, supervened only in 1884, and the seizures continue now at the rate of three or four a month. At all times he is subject to certain automatic tricks with his hands, putting and twisting them into various positions. Periodically almost during every day he gives exhibitions of the habit which has led him to be called the Der-

¹ *Reynolds's System of Medicine*, art. "Chorea."

² *Cycl. of Pract. Medicine*, art. "Chorea."

vish. He commences by tattooing his chin with his left hand; next he delicately and rapidly touches the fingers of his left hand to the wrist of the right, makes two or three salaams, and then impulsively gyrates the body from left to right. The right heel is pivotal, and the force is maintained by touches of the left toe or heel upon the floor. He will usually take from three to seven turns at a time, with a salaam or two between every series. Fifteen minutes or more will be thus consumed before he darts away toward a window, where he remains a few moments in a dazed state, from which he rouses to recommence his hand tricks. Perhaps he will select a broad belt of light in which to display his hand for visual enjoyment. He has a cataract of the right lens, and possibly partial amaurosis of the left eye. A supplemental performance sometimes indulged in is to stand at one fixed point and throw his head and shoulders from side to side, describing with the former two-thirds of a circle, the occiput being flexed backward as far as the neck will permit. These movements, rapidly made, reach three and four hundred under favorable conditions.

Kerlin regards the displays made by this boy to be the pure automatic phenomena of idiocy which have been developed to an artistic finish, and out of which the patient gets enjoyment. This enjoyment probably exists in some anæsthetic or stuporous condition of certain nerve-centres, something like the sensation of common dizziness. He does not look upon the case, therefore, as one of genuine catalepsy, but I have recorded it here in connection with the case just given because it illustrates a phase of automatism and rotation movements closely allied to cataleptoid conditions.

Catalepsy and Cataleptoid Phenomena among the Insane.

Catalepsy and cataleptoid or cataleptic phenomena are of comparatively frequent occurrence among the insane. Niemeyer says¹ that they are especially common among persons suffering from melancholia. Kahlbaum² has described a form of insanity which he names katatonia, from the Greek *κατατονω*, stretching down. This disease is "characterized by alternate periods, supervening with more or less regularity, of acute mania, melancholia, and epileptoid and cataleptoid states, with delusions of an exalted character and a tendency to dramatism."³

Kiernan⁴ has written a valuable memoir on this affection. He has collected fifty cases, a few of which he gives in detail. Hammond and Spitzka discuss the disorder, giving new cases, in their treatises on insanity.

Katatonia may begin in various ways, but it usually pursues a certain cycle. First appears stuporous melancholia, accompanied or followed by cataleptoid manifestations; then a period of mania with illusions, hallucinations, and delusions. Melancholia reappears in some form, with

¹ *Textbook of Practical Medicine*, Felix von Niemeyer, American trans., 1876, vol. ii. p. 387.

² *Klinische Abhandlungen über psychische Krankheiten*, 1 Heft, "Die Katatonie," Berlin, 1874.

³ *A Treatise on Insanity in its Medical Relations*, by William A. Hammond, M. D., New York, 1883, p. 576.

⁴ *American Journal of Insanity*, July, 1877, and *Alienist and Neurologist*, October, 1882.

cataleptoid, waxy condition of the muscles, and a disposition to talk in a pompous or dramatic manner; convulsions or choreic movements may be present.¹ Sometimes some phase of the cycle is absent.

In some cases in which the peculiar cycle and special phenomena which characterize katatonia are not present marked cataleptic or cataleptoid states may be observed among the insane, either as episodes or as long-continuing conditions.

As cases illustrating cataleptoid phenomena among the insane have not yet been published in large number, and are not well understood, I will record here, under the Symptomatology of Catalepsy, some illustrative cases which have either fallen under my own observation or have been supplied to me directly by medical friends.

M. A. Avery, assistant physician to the insane department of the Philadelphia Hospital, has kindly furnished notes of the following interesting case:

T—, aged twenty, single, dressmaker. The patient was somewhat below medium height, slender and emaciated, of nervous temperament, expression melancholy. The attack of insanity for which she was admitted was her first. It began four months before admission. No satisfactory history of the attack could be obtained; she was said to have been depressed in spirits and to have delusions of poisoning. She had attempted suicide by throwing herself from the window.

Upon admission, Sept. 20, 1883, she was quiet and gentle in her manner, but much depressed; she answered questions rationally. No delusions were detected. Sept. 21st she sat quiet and motionless. Her eyes were fixed, with marked double, inward squint. She was apparently insensible to external impressions. This condition lasted about three hours, when she suddenly sprang up, rushed through the ward, and made vigorous efforts to escape. On the 22d she lay in bed in a perfectly passive state, with eyes open and fixed, but the squint had disappeared. There was a constant slight tremor of the lids. The conjunctiva was apparently insensible to touch. She seemed to be unconscious of what was going on around her. Her arms remained raised in any position in which they were placed. About three o'clock in the afternoon this condition passed away, and from that time until she went to bed at eight o'clock she was bright and cheerful and talked in a rational and intelligent manner. For five days she was quiet and melancholy, with one spell of a few hours in which she was in a passive and cataleptic state, as on the 22d.

On the 28th she stood erect with arms extended, whirling rapidly. She continued this for about half an hour, and then, after a short rest, began again. She paid no attention to what was said to her, and seemed unconscious of what took place around her. The next day she remained in a stupid condition most of the time, but occasionally sprang up and danced violently or spun round rapidly with arms extended for a few moments at a time. On the 30th her cataleptic condition was uninterrupted. She lay motionless, with pulse slow and feeble, extremities cold; her limbs were easily placed in any desired position, and remained so for about twenty minutes; then they returned slowly to a more natural and comfortable position. She continued for several days in this condition, then aroused and ate heartily. She seemed brighter and more cheerful,

¹ Hammaond.

and talked rationally. She said that she knew all that was said and done when she seemed unconscious, and that she wanted to speak, but could not. For several weeks cataleptic symptoms prevailed, with occasional lucid intervals of a few hours. She eventually settled into a childish, demented condition.

In the insane department of the Philadelphia Hospital was a middle-aged man who remained for several years in a stuporous and cataleptoid state. On several occasions he was before the class in the clinic-room. He could not be made to speak, but remained perfectly silent in any condition in which he was placed. His head and trunk could be bowed forward, sideway, or backward; one foot could be elevated while he stood; his arms could be placed in grotesque positions. In whatever attitude he was placed he would remain for a long time. The only history that could be obtained of this man was that he had for several months been in a state of melancholia, after which he was maniacal for three or four months. He escaped from the hospital, and was brought back in the stuporous and cataleptoid condition in which he continued. He had been a masturbator.

A Dane, while on a voyage from Copenhagen, fell and broke his leg, for which he was treated in a hospital. He recovered and became a nurse in the institution. He fell in love with a female nurse, and was to be married, but the lady suddenly fell dead. He became melancholic, and three weeks afterward tried to hang himself. He also had hystero-epileptic seizures, and was for a long time in a condition of extreme stupor with cataleptoid phenomena, from which he passed into a rather excited condition. He had no special delusions, but there was a tendency to dramatism.

Another case came into the nervous wards of the Philadelphia Hospital. No history could be obtained from the patient. Whether or not he had previously suffered from melancholia could not be learned. He would retain for a long time any position in which he was placed. He also had hystero-cataleptic spells, and a peculiarity of enunciation with a tendency to pose. When asked, "How are you to-day?" he would reply, "I pre-sume-that-I-am-a-bout-the-same—that-it-is-likely-that-some-thing-has-dis-ap-peared-in-the-mind." When asked, "How long have you been sick?" he would begin in the same way: "I-pre-sume-that-I-will-have-to-say-that-at-a-time-re-mote-ly-dis-tant;" and then he would branch off into something else.

Wilks¹ speaks of a man whom he saw in the asylum at Morningside who could be moulded into any position. While in bed on his back his arms and legs could be arranged in any position, and there they would remain. He also speaks of a case seen by Savage in Bethlem—a young man who kept his arms stretched out for two hours, and stood on one leg for a very long time or until he fell.

William Barton Hopkins of Philadelphia has given me brief details of a case observed by him at the Pennsylvania Hospital, which would seem to have been either one of katatonia or one of cataleptoid attacks occurring in an inebriate. The patient was an habitual moderate drinker. For three weeks before he was admitted to the hospital he had been drinking heavily. His family history showed a tendency to insanity. He showed

¹Lectures on Diseases of the Nervous System, delivered at Guy's Hospital.

great mental anxiety; his face was pale and had a very troubled aspect. He had no hallucinations. Two days after admission a sudden outbreak of mania occurred, in which he showed destructive and dangerous tendencies, and mechanical restraint had to be employed. Under treatment he became quiet, and was removed by his friends, having been altogether five days in the hospital. On the day of his departure, while awaiting some of his friends in the main hall, he suddenly ran up stairs, and was quickly followed by a nurse, who found him raising a window with the apparent intention of jumping out. His face at this time had lost its troubled look, and had rather a pleased but vacant appearance. While in this condition his limbs were placed in various positions, and there remained. On another occasion, while lying on the bed, his limbs and trunk were placed in various grotesque positions, and there remained. The condition of waxen flexibility was well marked; many tests were made.

To Wharton Sinkler I am indebted for the unpublished notes of the case of a woman twenty-seven years of age, who had no family history of insanity, but whose father was a highly nervous man. She had always had good health, and was of good physique. Seven years ago she had an attack of melancholia lasting four or five months; since then she had no trouble until six months since. At this time she began to be low-spirited. Then delusions came on—that she was unworthy to live; that it was wicked for her to eat, because no one else had food; that those about her were in ill-health. She refused to eat, and would not talk, and slept badly. When first seen by Sinkler she was stout and with apparently good nutrition, but was said to have lost flesh. Her face was expressionless, and she was unwilling to converse, but said she was quite well, and that her stepmother was ill and needed treatment. She was undecided in all her movements, and would stand in one spot until led to a chair, where she would remain if seated.

The patient was placed under the care of two nurses, and for a week improved daily—ate food, conversed, read aloud, and sewed. At the end of this time she was left with one nurse, but became obstinate about eating, and had an altercation with the nurse, in which she became violent. After this she gradually got into a cataleptoid state. At first she would stand for a long time in one place, and if seated in a chair would remain in any position in which she was placed. She began to have attacks in which she would lie on the floor motionless for hours. A sharp faradic current was applied to the forearms on one occasion, and she soon became relaxed. In the attacks the eyes were closed or rolled upward and fixed on the ceiling. The muscles were rigid. The arms and legs could be placed in any attitude, and would there remain. There was no analgesia: she had decided objection to pin-pricks. For two or three days she was readily aroused from the cataleptic state by electricity, but it lost its effect, and etherization was resorted to. The first time a few whiffs of ether relaxed the rigid limbs. The next day the rigidity continued until complete etherization was effected. In fact, when the breathing was loudly stertorous and the conjunctiva insensible to touch, the rigidity was complete, and it was not until a large amount of ether had been inhaled that the limbs relaxed. While under the effects of the ether a vaginal examination was made, and the uterus found normal in position and size. No evidences

of self-abuse were found, nor had there been any reason for suspecting this. She continued in the condition described for many days. She was filthy in her habits, and would not use the commode, although she was made to sit on it for hours. She would have a stool on the floor or in bed immediately after rising from the commode. She seemed imbecile, and scarcely spoke, or, if she did, would say she was dead or was a baby. She would eat nothing voluntarily: food was put into her mouth, and she would swallow it, but made no effort to close the lips herself. She was fed in this way for four or five weeks. If taken up to be dressed, she would make the procedure as difficult as possible, and when dressed would not let her clothing remain buttoned, so that her clothes had to be sewed on her.

After about ten weeks a slight improvement showed itself, first in her taking food voluntarily, then in speaking. By degrees she became reasonable, and in about four months from the time she was first seen was perfectly well. The medication used was very slight, but she was thoroughly fed, took bromide of sodium and ergot for a time, and occasionally a dose of paraldehyde to produce sleep. She had two efficient nurses, who carefully carried out all directions, and who never yielded a point, but tried to be always as kind as firm. This case is instructive, not only because of its phenomena, but also because of the method of feeding and managing the patient and the result of treatment.

At a meeting of the Philadelphia Neurological Society held February 22, 1886, I exhibited, at the request of Dr. C. P. Henry, of the Insane Department of the Philadelphia Hospital, a case presenting cataleptoid symptoms, the phenomena of automatism at command, and of imitation automatism.

This patient had been recently admitted to the hospital, and no previous history had been obtained. He was a middle-aged man, not unintelligent-looking, and in fair physical condition. His condition and his symptoms had remained practically the same during the short time that had elapsed since admission. He remained constantly speechless, almost continually in one position; would not open his eyes, or at least not widely; would not take food unless forced; and his countenance presented a placid but not stupid or melancholy appearance. He had on several occasions assumed dramatic positions, posing and gesticulating. It had been discovered by Henry that the patient's limbs would remain where they were placed, and that he would obey orders automatically. The case had been regarded as probably one of katatonia, but in the absence of previous history it was not known whether or not he had passed through the cycle of mania, melancholia, etc. which constitutes this fully-developed disease. He had had since admission attacks of some severity, probably, from description, hystero-epileptic in character.

In exhibiting the patient I first placed his arms and legs and body and head in various positions, where they remained until he was commanded to place them in other positions. His mouth was opened, one eye was opened and the other was shut, and he so remained until ordered to close his mouth and eyes. In most of these experiments the acts performed were accompanied by remarks that the patient would do thus and so as he was directed.

Various experiments to show automatism at command were performed.

I remarked, for instance, that the gentleman was a good violin-player, when he immediately proceeded to imitate a violin-player. In a similar way he took a lead-pencil which was handed to him and performed upon it as if it were a flute. He danced when it was asserted that he was an excellent dancer; placed his arms in a sparring position and struck out and countered on telling him that he was a prize-fighter; went through many of the movements of drilling as a soldier, such as attention, facing, marking time, and marching. He was told that he was a preacher and must preach, and immediately began to gesticulate very energetically, as if delivering an earnest exhortation. He posed and performed histrionically when told that he was an actor. He was given a glass of water and told that it was good wine, but refused to drink it, motioning it away from him. He was then told that it was very good tea, when he tasted it, evincing signs of pleasure. During all these performances he could not be induced to speak; his eyes remained closed, or at least the eyelids drooped so that they were almost entirely closed. He showed a few phenomena of imitation, as keeping time and marching to the sound of the feet of the operator.

In the nervous wards of the Philadelphia Hospital there is now an interesting case of melancholia with catalepsy and the phenomena of automatism at command—a man aged twenty-five, white, single, who for thirteen years had worked in a type-foundry. Three years before coming to the hospital he had an attack of acute lead-poisoning with wrist-drop. Two years later he had an attack of mental excitement with other evidences of insanity. He had hallucinations of sight and hearing, and thought that he heard voices accusing his sister of immorality. He at times accused this sister of trying to poison him. He believed that his fellow-workmen were trying to have him discharged. This condition lasted for six weeks, when he became gloomy and stuporous, and would make no effort to do anything for himself. His friends had to feed him. When first admitted to the nervous wards he sat in the same position all day long, with his head almost touching his knees, his arms fully extended by his sides. He would not help himself in any way. His eyes were always open, and he never winked. He never slept any during the day, but was perfectly oblivious to all surroundings. He did not speak or move out of any position in which he was placed. He could be placed in all sorts of uncomfortable positions, and would remain in them. After treatment with strong electrical currents and forced exercise he brightened considerably, and would walk, after being started, without urging. When treatment was discontinued, he relapsed into his former state. Frequent experiments have been performed with this man. Placing his limbs in any position, they will remain if a command is given to retain them. He marches, makes movements as if boxing, etc. at command.

The phenomena shown by both of these patients are those which have for many years been known and described under various names. I well remember when a boy attending a series of exhibitions given by two travelling apostles of animal magnetism, in which many similar phenomena were shown by individuals, selected apparently at haphazard from a promiscuous audience, these persons having first undergone a process of magnetizing or mesmerizing. In experiments of Heidenhain of Bres-

laid upon hypnotized individuals many similar phenomena were investigated, and described and discussed by this physiologist under the names of automatism at command and imitation automatism. The hypnotized subjects, for instance, were made to drink ink, supposing it to be wine, to eat potatoes for pears, to thrust the hand into burning lights, etc. They also imitated movements possible for them to see or to gain knowledge of by means of hearing or in any other way. They behaved like imitating automatons, who repeated movements linked with unconscious impressions of sight or hearing or with other sensory impressions. It was noted in the experiments of Heidenhain that the subjects improved with repetition. The manifestations of my patients, although not simulated, improved somewhat by practice. Charcot, Richer, and their confrères have made similar observations on hysterical and hypnotized patients, which they discuss under the name of suggestion. Hammond¹ suggested the term *suggignoskism*, from a Greek word which means to agree with another person's mind, as a proper descriptive designation for these phenomena. In referring to persons said to be in one of the states of hypnosis, he says that he does not believe that the terms hypnotism and hypnosis are correct, as, according to his view, the hypnotic state is not a condition of artificial somnambulism; the subject, he believes, is in a condition where the mind is capable of being affected by another person through words or other means of suggesting anything. In the clinical lecture during which these opinions were expressed he is reported to have performed on four hypnotized young men experiments similar to those which were exhibited by my insane patients. His subjects, however, were not insane. A bottle was transformed by suggestion into a young lady; sulphur was transmuted into cologne; one of the subjects was bent into all sorts of shapes by a magnet; another was first turned into Col. Ingersoll and then into an orthodox clergyman, etc. In reading such reports, and in witnessing public exhibitions of the kind here alluded to, one often cannot help believing that collusion and simulation enter. Without doubt, this is sometimes the case, particularly in public exhibitions for a price; but what has been observed in the mentally afflicted, what has been shown again and again by honest and capable investigators of hypnotism, prove, however, not only the possibility, but the certainty, of the genuineness of these phenomena in some cases.

Catalepsy and this automatism at command are sometimes confused, or they may both be present in the same case; indeed, they are probably merely gradations of the same condition, although it is well to be able to differentiate them for the purposes of more careful and accurate investigation. In automatism at command the individual does what he is directed as long as he remains in this peculiar mental condition. In experimenting upon him, his arms or legs, his trunk or head, may be put in various positions, and if commanded to retain them in these positions he will do so, or he will, at command, put them in various positions, there to stay until a new order is given. Imitation automatism occurs also in such cases; patients will imitate what they see or hear. These cases differ only from those of genuine catalepsy in that they do not seem to present true waxen flexibility. The phenomena presented are those

¹ *Med. and Surg. Reporter*, vol. xlv., Dec. 10, 1881.

which result from control over an easily-moulded will, rather than phenomena due to the fact that the will is entirely in abeyance.

PATHOLOGY.—Attempts to explain the nature of catalepsy leave one in a very uncertain and irritable frame of mind. Thus, we are told very lucidly that most authors are inclined to the opinion that the cataleptic rigidity is only an increase of the normal tonus of the voluntary muscles occurring occasionally in the attacks. What appears to be present in all genuine cases of catalepsy is some absence or abeyance of volition or some concentration and circumscription of cerebral activity. The study of the phenomena of catalepsy during hypnosis throws some light upon the nature of catalepsy. Heidenhain's theory of hypnotism is that in the state of hypnosis, whether with or without cataleptic manifestations, we have inhibition of the activity of the ganglion-cells of the cerebral cortex. Herein is the explanation of many cataleptic phenomena even in complicated cases. In hysteria and in catalepsy the patient, dominated by an idea or depressed in the volitional sphere by emotional or exhausting causes, no longer uses to their full value the inhibitory centres. When organic disease complicates catalepsy, it probably acts to inhibit volition by sending out irritative impulses from the seat of lesion.

DURATION.—Usually, attacks of catalepsy recur over a number of years; but even when this is the case the seizures are not as frequent, as a rule, as those of hystero-epileptic paroxysms. Uncomplicated cases of catalepsy, or those cases which occur in the course of hystero-epilepsy, usually preserve good general health.

Of the duration of attacks of catalepsy it need only be said that they may last from a few seconds or minutes to hours, days, weeks, or even months. The liability to the recurrence of cataleptic attacks may last for years; and then disappear.

DIAGNOSIS.—In the first place, the functional nervous disorder described as catalepsy must be separated from catalepsy which occurs as a symptom in certain organic diseases. It is also necessary to be able to determine that a patient is or is not a true katatonic.

It must not be forgotten that genuine catalepsy is very rare. Mitchell at a recent meeting of the Philadelphia Neurological Society said that in his lifetime he had seen but two cases of genuine catalepsy—one for but a few moments before the condition passed off. The other was most extraordinary. Many years ago he saw a young lady from the West, and was told not to mention a particular subject in her presence or very serious results would ensue. He did mention this subject, rather with the desire to see what the result would be. She at once said, "You will see that I am about to die." The breath began to fail, and grow less and less. The heart beat less rapidly, and finally he could not distinguish the radial pulse, but he could at all times detect the cardiac pulsation with the ear. There was at last no visible breathing, although a little was shown by the mirror. She passed into a condition of true catalepsy, and to his great alarm remained in this state a number of days, something short of a week. Throughout the whole of this time she could not take food by the mouth. Things put in the mouth remained there until she suddenly choked and threw them out. She apparently swallowed very little. She had to be nourished by rectal alimentation. She was so remarkably cataleptic that if the pelvis were raised, so that

the head and heels remained in contact with the bed, she would retain this position of opisthotonos for some time. He saw her remain supported on the hands and toes, with feet separated some distance, with the face downward, for upward of half an hour. She remained as rigid as though made of metal. On one occasion while she was lying on her back he raised the arm and disposed of the fingers in various ways. As long as he watched the fingers they remained in the position in which they had been placed. At the close of half an hour the hand began to descend by an excessively slow movement, and finally it suddenly gave way and fell. Not long after this she began to come out of the condition, and quite rapidly passed into hysterical convulsions, out of which she came apparently well. He was not inclined to repeat the experiment.

Catalepsy is to be diagnosticated from epilepsy. It is not likely that a grave epileptic seizure of the ordinary type will be mistaken by an observer of even slight experience for a cataleptic attack. It is some of the aberrant or unusual types of epilepsy that are most closely allied to or simulate catalepsy. Cataleptic or cataleptoid conditions undoubtedly occur regularly or irregularly in the course of a case of epilepsy, but I do believe that it is true, as some observers contend, that between catalepsy and some types of true epilepsy no real distinction can be made. Hazard,¹ in commenting on a case reported by Streets,² holds that no difference can be made between the attacks detailed and those forms of epilepsy described as *petit mal*.

The case was that of a sailor aged forty-two years, of previous good health. The attacks to be described followed a boiler explosion, by which he was projected with great force into the water, but from which he received no contusion nor other appreciable injury. There was no history of any nervous trouble in his family. It was the patient's duty to heave the lead. The officer noticed that he was neglecting his business, and spoke to him in consequence, but he paid no attention to what was said to him. "He was in the attitude he had assumed in the act of heaving the lead, the left foot planted in advance, the body leaning slightly forward, the right arm extended, and the line held in the left hand. The fingers were partially flexed, and the sounding-line was paying out through them in this half-closed condition. The eyes were not set and staring, as is the case in epilepsy, but they were moving about in a kind of wandering gaze, as in one lost in thought with the mind away off. The whole duration of the trance was about five minutes."

Dickson³ reports a very striking case, and in commenting on it holds to the same views. The patient had apparently suffered from some forms of mania with delusions. She was found at times sitting or standing with her body and limbs as rigid as if in rigor mortis, and her face blanched. These spells were preceded by maniacal excitement and followed by violence. On being questioned about the attacks, she said that chloroform had been given her. Numerous experiments were performed

¹ *St. Louis Clin. Rec.*, iii, 1876, p. 125.

² "Case of Natural Catalepsy," by Thomas H. Streets, M. D., Passed Assistant Surgeon U. S. N., in the *American Journal of Medical Sciences* for July, 1876.

³ "On the Nature of the Condition known as Catalepsy," by J. Thompson Dickson, M. A., M. B. (Cantab., etc.), *British Med. Journ.*, vol. ii., Dec. 25, 1869.

with her. Her arms and hands were placed in various positions, in all of which they remained; but it was necessary to hold them for a few moments in order to allow the muscles to become set. She was anæsthetic. After recovering she said that she remembered being on the bed, but did not know how she came there; also, that she had been pricked with a pin, and that her fit had been spoken of as cataleptic. Her mind became more and more affected after each attack, and she finally became more or less imbecile. From the facts observed with reference to this case, Dickson thinks that we may fairly conclude that the mental disturbance in either epilepsy or catalepsy is identical, and results from the same cause—viz. the anæmia and consequent malnutrition of the cerebral lobes; while its termination, dementia, is likely to be the same in either case; also, that catalepsy, instead of being a special and distinct form of nervous disorder, is to be considered as a specific form of epilepsy, and to be regarded as epilepsy, in the same manner as *le petit mal* is considered epilepsy, and a result of the same proximate cause; the difference in the muscular manifestation bearing comparison with any other specific form of epilepsy, and occurring in consequence of one or other particular cerebral centre becoming more or less affected.

I do not believe that this ground is well taken. The conditions present in *petit mal* are sometimes somewhat similar to, but not identical with, those of genuine catalepsy. In the first place, the loss of consciousness, although more complete and more absolute—or rather, strictly speaking, more profound—than in genuine catalepsy, is of much briefer duration. The vertigo or vertiginous phenomena which always accompany genuine *petit mal* are rarely if ever present in catalepsy. To say that the mental disturbance in catalepsy and in epilepsy is identical is to admit an imperfect acquaintanceship with both disorders. The mental state during the attack of either disorder it is only possible to study by general inspection or by certain test-experiments.

Tetanus is not likely, of course, to be mistaken for catalepsy, but there is a possibility of such an occurrence. The differential diagnosis already given between hystero-epilepsy and tetanus will, however, furnish sufficient points of separation between catalepsy and tetanus.

Catalepsy has been supposed to be apoplexy, or apoplexy catalepsy. The former mistake is, of course, more likely to be made than the latter. A careful study of a few points should, however, be sufficient for the purposes of clear differentiation. The points of distinction given when discussing the diagnosis of hysterical and organic palsies of cerebral origin will here apply. In true apoplexy certain peculiar changes in pulse, respiration, and temperature can always be expected, and these differ from those noted in catalepsy. The stertorous breathing, the one-sided helplessness, the usually flushed face, the conjugate deviation of the eyes and head, the loss of control over bowels and bladder, are among the phenomena which can be looked for in most cases of apoplexy, and are not present in catalepsy.

It is hardly probable that a cataleptic will often be supposed to be drunk, or a man intoxicated to be a cataleptic; but cases are on record in which doubts have arisen as to whether an individual was dead drunk or in a cataleptic stupor. The labored breathing, the fumes of alcohol, the absence of waxy flexibility, the possibility of being half aroused by

strong stimuli, will serve to make the diagnosis from catalepsy. The stupor, the anæsthesia, the partial loss of consciousness, the want of resistance shown by the individual deeply intoxicated, are the reasons why occasionally this mistake may be made.

Catalepsy is simulated not infrequently by hysterical patients. Charcot and Richer¹ give certain tests to which they put their cataleptic subjects with the view of determining as to the reality or simulation of the cataleptic state. They say that it is not exactly true that if in a cataleptic subject the arm is extended horizontally it will maintain its position during a time sufficiently long to preclude all supposition of simulation. "At the end of from ten to fifteen minutes the member begins to descend, and at the end of from twenty to twenty-five minutes at the most it resumes the vertical position." These also are the limits of endurance to which a vigorous man endeavoring to preserve the same position will attain. They have therefore resorted to certain experimental tests. The extremity of the extended limb is attached to a tambour which registers the smallest oscillations of the member, while at the same time a pneumograph applied to the chest gives the curve of respiratory movements. In the case of the cataleptic the lever traces a straight and perfectly regular line. In the case of the simulator the tracings at first resemble those of the cataleptic, but in a few minutes the straight line changes into a line sharply broken, characterized by instants of large oscillations arranged in series. The pneumograph in the case of the cataleptic shows that the respirations are frequent and superficial, the end of the tracings resembling the beginning. In the case of the simulator, in the beginning the respiration is regular and normal, but later there may be observed irregularity in the rhythm and amplitude of the respiratory movements—deep and rapid depressions, indicative of the disturbance of respiration that accompanies the phenomena of effort. "In short, the cataleptic gives no evidence of fatigue; the muscles yield, but without effort, and without the concurrence of the volition. The simulator, on the contrary, committed to this double test, finds himself captured from two sides at the same moment."

Chambers² says that no malingerer could successfully feign the peculiar wax-like yielding resistance of a cataleptic muscle. He speaks of using an expedient like that of Mark's. Observing that really cataleptic limbs finally, though slowly, yield to the force of gravity and fall by their own weight, he attached a heavy body to the extended hand of a suspected impostor, who by an effort of will bore it up without moving. The intention of the experiment was explained, and she confessed her fraud. This rough test, although apparently different, is in reality similar to that of Charcot and Richer. In both proof of willed effort is shown.

It must not be forgotten that in catalepsy, as has been already noted in hysteria, real and simulated phenomena may commingle in the same case; also, that upon a slight foundation of genuine conditions a large superstructure of simulated or half-simulated phenomena may be reared.

PROGNOSIS.—The prognosis of catalepsy is on the whole favorable. It must be admitted, however, that owing to the presence of neurotic or neuropathic constitution a tendency to relapse is present. Hystero-cata-

¹ *Journal of Nervous and Mental Diseases*, vol. x., No. 1, January, 1883.

² *Reynolds's System of Medicine*, vol. ii., No. 108.

lepsy tends to recover with about the same frequency as any of the other forms of grave hysteria. Those cases which can be traced to some special reflex or infectious cause, as worms, adherent prepuce, fecal accumulations, scars, malaria, etc., give relatively a more favorable prognosis. Cases complicated with phthisis, marasmus, cancer, insanity, etc. are of course relatively unfavorable.

TREATMENT.—The treatment of the cataleptic seizure is not always satisfactory, a remedy that will succeed in one case failing in another. Niemeyer says that in case of a cataleptic fit he should not hesitate to resort to affusion of cold water or to apply a strong electrical current, and, unless the respiration and pulse should seem too feeble, to give an emetic. The cold douche to the head or spine will sometimes be efficacious. In conditions of great rigidity and coldness of surface Handfield Jones recommends a warm bath, or, still better, wet packing. Chambers quotes the account of a French patient who without success was thrown naked into cold water to surprise him, after having been puked, purged, blistered, leeches, and bled. This treatment is not to be recommended unless in cases of certain simulation, and even here it is of doubtful propriety and utility. If electricity is used, it should be by one who thoroughly understands the agent. A galvanic current of from fifteen to thirty cells has been applied to the head with instantaneous success in hystero-epileptic and hystero-cataleptic seizures. A strong, rapidly-interrupted faradic current, or a galvanic current to the spine and extremities, sometimes succeeds and sometimes fails. Rosenthal reports that Calvi succeeded in relieving cataleptic stiffness in one case by an injection of tartar emetic into the brachial vein—a procedure, however, not to be recommended for general use. Inhalations of a few drops of nitrate of amyl is a remedy that should not be passed by without a trial; it is of great efficacy in the hysteroid varieties. Inhalation of ammonia may also be tried. A hypodermic injection of three minims of a 1 per cent. solution of nitroglycerin, as recommended for severe hystero-epileptic seizures, would doubtless be equally efficient in catalepsy.

Music has been used to control hysterical, hystero-epileptic, and cataleptic seizures. The French cases reported have all been of the convulsive types without loss of consciousness and those varieties in which the special sensibility sometimes persists, as in hystero-catalepsy, lethargy, and somnambulism. Music has been used as medicine from the times of Pythagoras to the present, although it can hardly be claimed to have attained a position of much prominence as a therapeutic agent.

In one case a vigorous application of fomentations of turpentine to the abdomen was promptly efficacious in bringing a female patient out of a cataleptic seizure.

Meigs, whose case of catalepsy produced by opium has been reported under Etiology, suggests that purgative medicines, used freely in the treatment of his case, might be advantageously resorted to in any case of catalepsy.

Powerful tonics, such as quinine, iron, salts of zinc and silver, should be used in connection with nutrients, such as cod-liver oil, peptonized beef preparations, milk, and cream, to build up cataleptic cases in the intervals between the attacks.

ECSTASY.

By CHARLES K. MILLS, M. D.

DEFINITION.—Ecstasy is a derangement of the nervous system characterized by an exalted visionary state, absence of volition, insensibility to surroundings, a radiant expression, and immobility in statuesque positions. The term ecstasy is derived from two Greek words, *ἐκ* and *στασις*, which means to be out of one's senses or to be beside one's self. Commonly, ecstasy and catalepsy, or ecstacy and hystero-epilepsy, or all three of these disorders, alternate, coexist, or occur at intervals in the same individual. Occasionally, however, the ecstatic seizure is the only disorder which attracts attention. Usually, in ecstasy the concentration of mind and the visionary appearance have reference to religious or spiritual objects.

SYNONYMS.—Trance is sometimes used as synonymous with ecstasy. While, however, ecstasy is a trance-like condition, conditions of trance occur which are not forms of ecstasy. Other synonyms are Carus-extasis, Catochus, Catalepsia spuria.

HISTORY AND LITERATURE.—Accounts of cases of ecstasy abound in both ancient and modern medical and religious literature. The epidemics of the Middle Ages, the days of the New England witchcraft, the revivals in England and America, have afforded many striking illustrations. Not a few special cases of ecstasy have become historical. Elizabeth of Hungary and Joan of Arc were both cataleptics and ecstasies. Saint Gertrude, Saint Bridget, Saint Theresa, Saint Catharine, and many other saintly individuals of minor importance have owed their canonization and their fame to the facility with which they could pass into states of ecstasy, catalepsy, or hystero-epilepsy.

Gibbon¹ has well described the occurrence of ecstasy in the monks of the Oriental Church in the following passage: "The fakirs of India and the monks of the Oriental Church were alike persuaded that in total abstraction of the faculties of the mind and body the purer spirit may ascend to the enjoyment and vision of the Deity. The opinions and practices of the monasteries of Mount Athos will be best represented in the words of an abbot who flourished in the eleventh century. 'When thou art alone in thy cell,' says the ascetic teacher, 'shut thy door and seat thyself in a corner; raise thy mind above all things vain and transitory; recline thy beard and thy chin on thy breast; turn thine eyes and thy thoughts toward the middle of thy belly, the region of the navel; .

¹ *Decline and Fall of the Roman Empire*, by Edward Gibbon, Esq., in 8 vols., vol. viii. p. 64, London, 1838.

and search the place of the heart, the seat of the soul. At first all will be dark and comfortless; but if you persevere day and night you will feel an ineffable joy; and no sooner has the soul discovered the place of the heart than it is involved in a mystic and ethereal light.' This light, the production of a distempered fancy, the creature of an empty stomach and an empty brain, was adored by the Quietists as the pure and perfect essence of God himself; and as long as the folly was confined to Mount Athos the simple solitaries were not inquisitive how the divine essence could be a material substance, or how an immaterial substance could be perceived by the eyes of the body. But in the reign of the younger Andronicus the monasteries were visited by Barlaam, a Calabrian monk, who was equally skilled in philosophy and theology, who possessed the languages of the Greeks and Latins, and whose versatile genius could maintain their opposite creeds according to the interest of the moment. The indiscretion of an ascetic revealed to the curious traveller the secrets of mental prayer, and Barlaam embraced the opportunity of ridiculing the Quietists, who placed the soul in the navel—of accusing the monks of Mount Athos of heresy and blasphemy."

Some of Swedenborg's supernatural visions were, so far as can be judged, simply accounts of attacks of ecstasy; and of like character were the visions of John Engelbrecht as related by Arnold.¹

In a very curious American book² published in 1815 a history is given of the wonderful performances of a woman named Rachel Baker, who was undoubtedly in the habit of passing into conditions of religious ecstasy, during which were present many of the phenomena which occur in ecstasies, Catholic or Protestant, religious or otherwise. When seventeen years old she witnessed the baptism of a young lady, which impressed her strongly and caused her to become much dejected and affected about her religious state. She began to have evening reveries or night talks which soon attracted attention. She united with the Presbyterian Church. These reveries after a while expanded into evening exercises which began with prayer, after which she exhorted and made a closing prayer. She removed from Marcellus to Scipio, New York, in 1813, and shortly afterward, in the same year, she went to New York City for medical advice. While there she gave many opportunities to witness her powers when in what her editors quaintly call her somnial paroxysms. Her discourses were good illustrations of what is sometimes termed trance-preaching.

One of the most interesting parts of this curious book is a dissertation by Samuel L. Mitchill, M. D., on the function of somnium. He says there are three states of animal existence—wakefulness, sleep, and vision or dream. The definition of somnium, which he quotes from Cicero, is a very fair one to be applied to some of the conditions which we now speak of under such heads as lethargy, trance, ecstasy, etc. "By somnium," he says, "may be understood the performance of certain mental and bodily actions, which are usually voluntary, without the direction or government of the will or without the recollection afterward that such volition existed." He divides somnium into symptomatic and idio-

¹ *Observations, etc.*, London, 1806.

² *Devotional Somnium; or, A Collection of Prayers and Exhortations Uttered by Miss Rachel Baker, by Several Medical Gentlemen*, New York, 1815.

pathic. The symptomatic somnium occurs from indigestion, the nightmare, from affusions of water into the chest, from a feverish state of the body, from debility with fasting, from fresh and vivid occurrences, etc. The idiopathic somnium is divided into somnium from abstraction, somnium with partial or universal lunacy, with walking, with talking, with invention, with mistaken impressions of sight and of hearing, with singing, with ability to pray and preach or to address the Supreme Being and human auditors in an instructive and eloquent manner, without any recollection of having been so employed, and with utter incompetency to perform such exercises of devotion and instruction when awake. To the last of these affections he refers the case of Rachel Baker, whose devotional somnium he describes.

A number of other curious cases are recorded in this book: that of Job Cooper, a weaver who flourished in Pennsylvania about the year 1774; that of the Rev. Dr. Tennent, who came near having a funeral in one of his states of trance, who has related his own views, apprehensions, and observations while in a state of suspended animation. He saw hosts of happy beings; he heard songs and hallelujahs; he felt joy unutterable and full of glory: he was, in short, in a state of ecstatic trance. Goldsmith's history of Cyrillo Padovando, a noted sleep-walker, who was a very moral man while awake, but when sleep-walking a first-class thief, robber, and plunderer of the dead, is also given.

One of the most remarkable instances of ecstasy is that of the girl Bernadette Soubirons, whose wonderful visions led to the establishment of the now famous shrine of Our Lady of Lourdes in the south of France. It is related of this young girl by her historian Lasserre¹ that when about to cross the Gave, a mountain-stream of the Pyrenees, she suddenly saw in a niche of a rock a female figure of incomparable splendor, which she described as a real woman with an aureola about her head and her whole body of surprising brightness. The child afterward described in detail the vision she had seen. Later, on a number of occasions at the same spot, she saw the same vision, described as appearing transfigured. The child believed that she saw the Immaculate Virgin. The Virgin told her that she wished a church to be built on the spot. The place has since become a shrine for Catholics of all nations.

Meredith Clymer² has written an elaborate communication on ecstasy. Ambrose Paré, quoted by Clymer, defines ecstasy as a reverie with rapture of the mind, as if the soul was parted from the body. Briquet describes it as a state of cerebral exaltation carried to such a degree that the attention, concentrated on a single object, produces the temporary abolishment of the other senses and of voluntary movements.

ETIOLOGY.—Under the predisposing causes of ecstasy may be comprised almost all of those described under hysteria. The predisposition to the development of ecstasy will be governed in great measure by peculiarities of religious education and of domestic and social environment.

Extreme religious feeling is undoubtedly among the most frequent of

¹ *Our Lady of Lourdes*, by Henri Lasserre, translated from the French, 7th ed., New York, 1875.

² "Notes on Ecstasy and other Dramatic Disorders of the Nervous System," *Journal of Psychological Medicine*, vol. iv., No. 4, October, 1870.

the exciting causes of ecstasy. The accidents and incidents of love have also had a place. Sexual excitement is sometimes associated with the production of ecstasy. "In pre-Christian times," says Chambers, "when, in default of revelation, men worshipped their incarnate passions, we have from the pen of Sappho a description of a purely erotic ecstasy which can never be produced again." Fear or fright has been known to throw a predisposed individual into an attack of ecstasy. Severe threats have occasionally had the same influence.

SYMPTOMATOLOGY.—In considering the symptomatology of ecstasy it will only be necessary to call attention to the ecstatic attack. The accompanying phenomena are those of hysteria, hystero-epilepsy, etc., already fully described. I cannot do better than quote from Lasserre the account of one of the ecstatic seizures of Bernadette Soubirons. Although given in turgid language and from the religious point of view, the description is a good one of the objective phenomena of ecstasy:

"A few moments afterward you might have seen her brow light up and become radiant. The blood, however, did not mantle her visage; on the contrary, she grew slightly pale, as if Nature somewhat succumbed in the presence of the apparition which manifested itself to her. All her features assumed a lofty and still more lofty expression, and entered, as it were, a superior region, a country of glory, significant of sentiments and things which are not found below. Her mouth, half open, was gasping with admiration and seemed to aspire to heaven. Her eyes, fixed and blissful, contemplated an invisible beauty, which no one else perceived, but whose presence was felt by all, seen by all, so to say, by reverberation on the countenance of the child. This poor little peasant-girl, so ordinary in her habitual state, seemed to have ceased to belong to this earth.

"It was the Angel of Innocence, leaving the world for a moment behind and falling in adoration at the moment the eternal gates are opened and the first view of paradise flashes on the sight.

"All those who have seen Bernadette in this state of ecstasy speak of the sight as of something entirely unparalleled on earth. The impression made upon them is as strong now, after the lapse of ten years, as on the first day.

"What is also remarkable, although her attention was entirely absorbed by the contemplation of the Virgin full of grace, she was, to a certain degree, conscious of what was passing around her.

"At a certain moment her taper went out; she stretched out her hand that the person nearest to her might relight it.

"Some one having wished to touch the wild rose with a stick, she eagerly made him a sign to desist, and an expression of fear passed over her countenance. 'I was afraid,' she said afterward with simplicity, 'that he might have touched the Lady and done her harm.'"

Side by side with this description by the devout Lasserre of the appearance presented by Bernadette when in a state of ecstasy, I will quote the often-recorded account which Saint Theresa has given in her *Memoirs* of her subjective condition while in a similar state:

"There is a sort of sleep of the faculties of the soul, understanding, memory, and will, during which one is, as it were, unconscious of their working. A sort of voluptuousness is experienced, akin to what might

be felt by a dying person happy to expire on the bosom of God. The mind takes no heed of what is doing; it knows not whether one is speaking or is silent or weeping; it is a sweet delusion, a celestial frenzy, in which one is taught true wisdom in a way which fills us with inconceivable joy. We feel as about to faint or as just fallen into a swoon; we can hardly breathe; and bodily strength is so feeble that it requires a great effort to raise even the hands. The eyes are shut, or if they remain open they see nothing; we could not read if we would, for, though we know that they are letters, we can neither tell them apart nor put them together, for the mind does not act. If any one in this state is spoken to, he does not hear; he tries in vain to speak, but he is unable to form or utter a single word. Though all external forces abandon you, those of the soul increase, so as to enable you the better to possess the glory you are enjoying."

Occasionally striking illustrations of ecstasy are to be found among hysterical and hystero-epileptic patients in whom religious faith has no place. In these cases usually other special phases of grave hysteria are present. In some of the descriptions given by Charcot and Richer of hystero-epileptics in the stage of emotional attitudes or statuesque positions the patients are, for a time at least, in an ecstatic condition in which the hallucinations may be connected with sentiments of religion, love, fear, or other emotions. One shows an attitude of menace or an expression of fear; in another the expression is of beatitude or saintly happiness: to this expression perhaps succeeds one of intense joy; to this, one of passion and lubricity. Throughout all the changing phases of attitude and expression the patient has the other concomitants of the true ecstatic state, such as want of volition and insensibility.

DIAGNOSIS.—A cataleptic may also be an ecstatic or the reverse; but not a few cases are on record in the history of which, on the one hand, an individual has been subject over a long period to cataleptic seizures without the recurrence of ecstasy, or, on the other hand, to fits of ecstasy without a single attack of true catalepsy. Cataleptic attacks usually occur with more suddenness than ecstasy; the cataleptic may suddenly become rigid and statuesque—the ecstatic gradually, although it may be somewhat rapidly, passes step by step into a visionary state. In catalepsy and ecstasy the expression of the patient differs. One of the striking features of ecstasy is not simply the absorbed and abstracted, but also the radiant, expression of countenance. In catalepsy the expression is more likely to be vacant or at least negative. In ecstasy waxen flexibility is not present. The muscles can act in obedience to the will, and the trunk and limbs do not maintain the positions in which they are placed for any unusual time. In genuine catalepsy the consciousness is so suspended or altered that the period of the seizure afterward remains a blank in the memory of the patient. In ecstasy, however, the visions and fancies present during the fit can afterward be recalled, and are frequently recounted by the individual.

DURATION, COURSE, PROGNOSIS.—Nothing need be said as to duration, course, prognosis, etc. of ecstasy. The remarks made in considering hysteria, hystero-epilepsy, etc. fully cover these matters.

TREATMENT.—With reference to the treatment of ecstasy little need be said. It must, in part at least, be directed to rousing and changing

the dormant or dreamy condition of the individual. As it is the mind or the volitional nature which is chiefly affected, the use of agents which either directly or reflexly exert a powerful impression on the cerebral centres is indicated. Thus, in all ages harsh measures have received more or less applause in the treatment of ecstasy. The cold douche or shower-bath, the plunge-bath, the hot iron, painful electric currents, scourging, and beating have all had their advocates. Flint¹ gives details of a case in which burning with a heated hammer was employed for three weeks, the patient eventually recovering, either because of, or in spite of, the treatment. Chambers believes in the forcible repression of ecstatic and emotional exhibitions. "In Unst, the most northerly of the Shetland Islands," he says, "an epidemic of convulsive fits occurring in sermon-time began to prevail in several parish churches. At one of these, Northmaven, the disease was cut short by a rough fellow of a Turk who carried out a troublesome patient and tossed her into a wet ditch. Nobody else caught it. From what scandalous scenes Europe might have been saved had the first dancer on St. John's Eve been tossed into a wet ditch!"

Trance, Lethargy, and Morbid Somnolence.

Trance may be defined as a derangement of the nervous system characterized by general muscular immobility, complete mental inertia, and insensibility to surroundings. The condition of a patient in a state of trance has been frequently, and not inaptly, compared to that of a hibernating animal. Trance may last for minutes, hours, days, weeks, or even months. Astonishing stories, some true, others—and these the greater number—false, frequently find their way into newspapers. A recent story is that of a hystero-cataleptic young woman of Nebraska who is reported to have been for seventy days in a state of trance, during which she was to all appearance lifeless with the exception of respiration and pulsation. She said that she was unconscious during the whole time of her protracted trance, but, although she exerted her utmost power to evince her consciousness, she could not move a muscle. Such cases like the Welsh fasting girl either live or seem to live for a long time on little or no food; doubtless food is often taken secretly.

In an interesting case which, so far as I know, has never been put upon record in any medical publication, attacks of catalepsy or of trance, or of both, occurred three times at long intervals during the life of this individual. The first time was while held in the arms of his mother preparatory to receiving the baptismal rite: the clergyman and others observed that the infant changed appearance and suddenly became rigid. It was feared that he was dying; the ceremonies were stopped, but in response to efforts after a time he came back to a normal state. When about sixteen years of age, while at school, he was accidentally wounded; it was necessary to probe for the ball, and while this was being done he again passed into a trance-like condition. Many years later, while in good health, a prosperous and well-known citizen, he suddenly again fell into an unconscious condition, and was believed to be dead. So marked were the appearances of death

¹ *Loc. cit.*

that after numerous efforts to resuscitate him preparations were made for his funeral. The knowledge of his previous attacks, however, induced his friends and relatives to defer his interment and continue their efforts. He finally revived just as they were about to give up in despair.

Aëtius, according to Laycock,¹ mentions hysteric death as being very common in his day, and asserts that real death may supervene without any of the ordinary symptoms. The eyes preserve their brightness and the color of the skin remains vivid. Good cites the case of a woman whose funeral was postponed to ascertain the cause of her death, and whom the first touch of the scalpel brought to her senses. Authors and travellers have described wonderful cases of trance which have been observed in Persia and in India. A Persian youth is recorded to have possessed the power to restrain his breath for two days; and fakirs in India are said sometimes to have allowed themselves to be buried alive for weeks. Doubtless, a little Caucasian light let in upon some of these stories might dissolve them, as the esoteric Buddhism of Madame Blavatzky has been dissipated into thin air by a hard-headed English investigator. According to Diogenes,² Empedocles, a celebrated disciple of Pythagoras, obtained great fame by curing a female supposed to be dead, but whom he discovered to be suffering from hysteria. He termed the affection under which she labored apnoë, and maintained that a female might live in an apparently lifeless state for thirty days.

Landouzy has reported an interesting instance of lethargy produced by the application of a magnet to a patient suffering from hysteria major. The attacks of hysterical sleep are often preceded by convulsive phenomena, and, according to Briquet, are often ushered in by epileptoid signs, such as whistling inspiration, movements of deglutition, frothing, and transient rigidity of the limbs. Richer reports a remarkable case of Plendlers of Vienna, in which a young girl, after a series of violent hysterical attacks, fell apparently dead. Preparations were made to bury her, when she was found to be living, having been in a state of lethargy. Among cases observed in Salpêtrière the duration of lethargy has been from two to eight days. Sometimes, in cases of grave hysteria, attacks of lethargy complicated with general or partial contractures and epileptoid phenomena have been observed. The presence of neuro-muscular hyperexcitability is of diagnostic value in determining the nature of such cases; if present, we have probably to deal with phenomena of hysterical lethargy. This symptom may, of course, pass unperceived. A woman came under observation a short time since, being then far gone in pregnancy. About a month before delivery she had a very marked hysterical outbreak, in which she so simulated apoplexy as to make it almost impossible to decide what was the matter with her. She had apparently lost sensation, her breathing was stertorous, her pulse labored, and she had divergent strabismus. In the course of half an hour the symptoms passed off.

In trance, as in ecstasy, the patient may remain motionless and apparently unconscious of all surroundings; but in the former the visionary state, the radiant expression, and the statuesque positions are not necessarily present. In trance, as stated by Wilks, the patients may lie

¹ *Op. cit.*

² Quoted by Laycock.

like an animal hibernating for days together, without eating or drinking, and apparently insensible to all objects around them. In ecstasy the mind, under certain limitations, is active; it is concentrated upon some object of interest, admiration, or adoration. Conditions of trance, as a rule, last longer than those of ecstasy.

Beard's¹ theory of trance is that it is "a functional disease of the nervous system in which the cerebral activity is concentrated in some limited region of the brain, with suspension of the activity of the rest of the brain, and consequent loss of volition. Like other functional nervous diseases, it may be induced either physically or psychically—that is, by all the influences that act on the nervous system or on the mind; more frequently the latter, sometimes both combined."

T. D. Crothers² has contributed some papers upon the subject of the trance state in inebriety. He gives the clinical history of some cases of inebriety which presented the phenomena of cerebral automatism or trance. He concludes that loss of memory and consciousness may come on in inebriety and the patient give little or no evidence of his actual condition. His conclusions are, that when the trance state is established beyond doubt the individual is irresponsible for his acts during this period. The study of the trance state in affections of such definite origin and positive pathology as inebriety helps to throw light upon its occurrence and explanation in cases of hysteria.

Dana³ reports about fifty cases of prolonged morbid somnolence. Nearly all those reported previous to 1878 are cases of what has been termed trance-like sleep or lethargy. In 1878, Gelineau called attention to a disease which he termed narcolepsy. Dana has seen five cases, and reports two others from notes furnished by Putzel of New York. Some of the cases collected are both interesting and remarkable. Dana calls attention to the distinction made by Briquet between prolonged hysteria and lethargy. In lethargy the condition of unconsciousness is generally more profound, the reflexes are abolished, and the patient cannot be aroused. A patient may even have periods of sleep within the lethargy.

Dana excludes from his cases of prolonged somnolence those cases of drowsiness due to ordinary causes, as old age, diseased blood-vessels, cerebral malnutrition, or inflammation; various toxæmiæ, as malaria, uræmia, colæmia, and syphilis; dyspepsia, diabetes, obesity, insolation, cerebral anæmia and hyperæmia, cerebral tumors and cranial injuries, exhausting diseases, and the sleeping sickness of Africa.

He found that the prolonged somnolence shows itself in very different ways. Sometimes the patient suffers from simply a great prolongation of natural sleep; sometimes from a constant, persistent drowsiness, which he is often obliged to yield to; sometimes from frequent brief attacks of somnolence, not being drowsy in the intermission; sometimes from single or repeated prolonged lethargic attacks; finally, sometimes from period-

¹Quoted by Crothers in *Quarterly Journal of Inebriety*, January, 1880.

Beard, M. D., a paper read before the New York Medico-Legal Society, November 2, 1881, Hartford, Conn., 1882.

³"Morbid Drowsiness and Somnolence," *Journ. of Nervous and Mental Disease*, vol. xi., No. 2, April 18, 1884.

ical attacks of profound somnolence or lethargy which last for days, weeks, or months.

He says that most cases of functional morbid somnolence are closely related to the epileptic or hysterical diathesis; but a class of cases is met with in which no history or evidence of epilepsy or hysteria can be adduced, and though they may be called epileptoid or hysteroid, these designations are simply makeshifts; the patients seem to be the victims of a special morbid hypnosis. Possibly they have a cerebral hyperæmia or anæmia.

Under the name of morbid somnolence a case has been reported by P. J. Cremen.¹ The patient was a man fifty-five years old, who was admitted to the hospital under the care of Cremen. He said he had recently returned from America, where he had taken a drink which had affected his head. He went to bed, and the next morning was found in a deep sleep, from which he could not be aroused. He presented the appearance of a person in a sound sleep or under the influence of anæsthetics. All ordinary measures were unavailing to awaken him from his trance-like condition. He was completely analgesic over the entire surface of the body. He would not eat or drink when simply directed, but when the drinking-cup was placed in his hand he drank, and when bread or meat was given he ate. Subsequently he was seen eating while in the somnolent state with the eyes closed; but after a time he would stop, and had to be urged to commence again. Evidently, tactile sensibility was not lost. The muscular sense appeared to be diminished. The superficial reflexes were abolished, the knee-jerks exaggerated; ankle clonus was absent. Smell and taste were obtunded. Hearing was retained. The state of muscular rigidity during the somnolence was remarkable. He was placed between two chairs, the tip of the shoulder resting upon one chair, the heel of the left foot on the other, and the right leg bent at a right angle to the trunk. A weight of forty pounds was then supported on the rigid chest without causing the slightest yielding or movement from the position described until muscular relaxation took place. He often remained in this state for four or five days at a time or longer. He could be aroused by a strong magneto-electric current. In the intervals between the attacks he was sometimes bright and cheerful, at others gloomy and depressed. When requested to walk, he would do so in a perfectly straight line, from which he would not deviate for obstacles. When told to walk around a table, however, or other obstacle, he would do so. He would try to do anything that he was told, even to standing on his head. The somnolent or hypnotic state could be induced at will by closing the eyelids and pressing the eyeballs for about two minutes. Of the genuineness of the phenomena Cremen had no doubt; he believed that the somnolence partook, in some degree, of the nature of that which has been designated narcolepsy. This case in many respects is similar to cases of catalepsy and automatism at command. A very similar case has been reported in the article on Catalepsy.

Self-concentration in those of robust minds differs rather in degree than in essence from ecstasy or trance and allied conditions in the weak and hysterical. "Archimedes," says Clymer, "engrossed with a problem in

¹ *Brit. Med. Journ.*, Dec. 12, 1885.

geometry, feels no hunger and is deaf to the tumult of the soldiers in a captured town; Socrates, occupied with his own thoughts, stands twenty-four hours immovable in one spot exposed to the burning rays of the sun." Goethe, Blake, and others are on record as having the power to call up images at will. Francis Galton¹ in a recent work advocates the cultivation of this power of the reproduction at will of mental imagery. Clarke² records many wonderful instances of pseudopia. In what does the ecstatic differ from these except in that the mental status of the individual is different, and that the object of mental concentration is of a special character, consonant with the person's ideas, training, and surroundings?

In brown study or reverie, according to Laycock, the eye is fixed by a muscular action analogous to that of the cataleptic; and not the eye only, for a limb or the whole body will remain in the same position for many minutes, the senses themselves being in deep abstraction from surrounding objects.

Stigmatization.

Stigmatization (from the Greek *στυγμα*, a small puncture) is a symptom or appearance which usually presents itself in the form of bloody or blood-like markings on the palms of the hands, the backs of the feet, and the left side, the positions in which Christ was lacerated by the nails and the spear at the crucifixion. In some cases the stigmata are found in scattered points on various parts of the body, sometimes upon the forehead at the position of the lacerations produced by the crown of thorns. In various ages it has been claimed by Catholics that cases of genuine stigmatization have occurred. It is not, however, a matter of Catholic faith, the claim being simply that it is a genuine experience which has some supernatural significance. Hammond³ has an interesting chapter on the subject of stigmatization, of which I have made use, and Clymer's⁴ article, already referred to, gives the details of several of the most interesting historical cases. Space will not permit more than a glance at this subject. A case of stigmatization is not necessarily one of hysteria, but the phenomena of simulated, and possibly of genuine, stigmatization usually occur among the hysterical.

According to Garres, the first to exhibit stigmatization was Saint Francis of Assisium, who was born in 1186 and died in 1236. In 1224 he was marked, and in memory of the event the 17th of September was set apart as the Feast of the Holy Stigmata by Pope Benedict XI. The story of this occurrence is of a highly emotional and sensational character. Christine de Stumbele, born in 1242, a few miles from Cologne, is another of the famous hystero-cataleptics and ecstasies who were the victims of numerous stigmata. These were irregular as to position and to times of appearance. On one occasion, for instance, she had wounds on each foot from which the blood flowed freely; a little later, on the same

¹ *Inquiries into Human Faculty and its Development*, Francis Galton, F. R. S., New York, 1883.

² *Vision, a Study of False Sight*, by Edward H. Clarke, M. D., Boston, 1878.

³ *On Certain Conditions of Nervous Derangement*, New York, 1881.

⁴ *Op. cit.*

occasion, she was wounded on the knee, and to the wondering priest who was ministering to her at this time she showed hot nails of hideous shapes. She was not only a case of ecstasy and stigmatization, but a filthy creature withal, who covered herself and others with excrement, which they had the foolishness to believe came from the hand of the devil. Veronica Giuliani, another ecstatic, who conversed with Christ and the Virgin Mary, received the stigmata during one of her prayers, and was canonized in 1839. Imbert-Gourbeyre gives a list of 145 persons who have received stigmata, besides 8 now living known to him. He details one American case, that of a young French Canadian.

Two of the most extraordinary recent cases are those of Palma d'Oria and Louise Lateau. These have become stock cases in books and dissertations on the subject under consideration, and therefore the briefest accounts of them will be all that is required. Palma in 1871 was sixty-six years old, humpbacked, thin, small, and with light expressive eyes. It is important to note that she had seen Louisa Lateau in ecstasy. Wonderful accounts are given of her performances—eating the Host in the presence of the priest; having visions of the devil with a little horn on his forehead; on another occasion Jesus Christ himself bringing to her the communion; seeing the Host flying through the air before entering her mouth. After the communion, usually when others were not present, the stigmatization occurred. Bleedings from the forehead or near it, and hemorrhagic spots on various parts of the body of various shapes, as of hearts and of the cross, appeared. Examination of the skin subsequently showed it to be intact, except that she had a hole in the cranium, which Hammond suggests was of syphilitic origin. Plates are given in the work of the credulous Imbert-Gourbeyre representing these figures.

In most respects the most celebrated of all cases of stigmatization is that of Louise Lateau—celebrated because of the investigations which have been made of her case; because of the amount of literature, theological, scientific, and medical, which has been devoted to her; because of the conflict of opinions even among medical observers in regard to the true explanation of the phenomena she exhibited. Louise Lateau was a Belgian peasant-girl, born January 30, 1850. Her parents were poor. She suffered the hardships of her class, and was as badly nourished and educated as a poor Belgian peasant-girl is likely to be. During the cholera epidemic of 1866 she nursed kindly and patiently many of the victims. In 1867 she became weak, pale, and neuralgic, and sometimes spat blood. On Friday, April 24, 1868, she for the first time noticed blood immediately below the left breast; the following Friday it appeared at the same place, and also on the back of the left foot; later, it oozed from the left side and both feet, from the palms and backs of the hands, and from the forehead. Some weeks after this she began to exhibit the phenomena of ecstasy; and subsequently for months and years, regularly on every Friday, she had a recurrence of the stigmata and ecstasy, with accompanying phenomena, sometimes varying a little in detail. Some of the accounts given by Lefevre and others of her seizures are beautiful descriptions of attacks of ecstasy. She stated that during her attacks she had a distinct vision of the whole scene of the crucifixion.

Numerous experiments, some of them cruel in character, were per-

formed to test the genuineness of her conditions of unconsciousness and insensibility. Sight, hearing, and touch were tested. The mucous membrane of the nose was tickled; strong hartshorn was applied to the nostrils; she was pricked and stabbed with needles, pins, and even pen-knives; painful currents of electricity were used. To none of these did she respond. During her attacks her pulse was thready, ranging from 120° to 130° and upward; respiration sometimes could be scarcely detected, and sometimes fell as low as 10; body-heat was also much diminished. She recollected everything which passed during the attack. Different from Palma d'Oria, the examination of her skin revealed certain appearances. Between Saturday and Thursday oval spots and patches of rosy hue were to be seen on the backs and palms of the hands and on the backs and soles of the feet. They were very much in appearance as if the epidermis were thinned or scraped. The marks on the forehead were not permanent; the chest was only examined during the ecstasy. Before the bleedings blebs began to rise at the position of the spots. The bleeding commonly began in the night between Thursday and Friday. From the forehead of the girl blood sometimes oozed from minute points, which looked as if they had been made by microscopic leeches.

As regards the phenomena presented by Louise Lateau, various hypotheses have been advanced; the chief, however, are the three following: (1) The theological view—namely, that the stigmata were genuine miraculous performances, the blood flowing by supernatural command. (2) The view that the stigmata were genuine pathological phenomena, vaso-motor in character—that the bleedings were in some way similar to attacks of purpura hemorrhagica or to hæmidrosis or bloody sweat. (3) The view that the stigmata were produced by deceit—that in all probability, in order to excite the sympathy and astonishment which are so dear to the hysterical mind, the girl in some way caused the bleedings. The carefully detailed accounts of the phenomena seem to lend the strongest support to the last view.

A good test was employed for the detection of simulated stigmatization in the following case,¹ which came under the care of Mr. Henry Lee at St. George's Hospital, London. An unmarried seamstress aged sixteen had on the outside of her right leg above the ankle a discolored patch, from which she said that every month for two years there had been a discharge of about a tablespoonful of blood. The patch was covered with minute red spots resembling flea-bites. Fresh red spots and effusion of blood were seen at succeeding visits. Lee ordered a sheet of lead to be applied over the bleeding surface, to be secured by a starched bandage. On the next visit, when the dressings were removed, a few spots and a little blood were found, but the sheet of lead was pierced with holes large enough to admit a needle. When asked how this had happened the girl was silent, and was discharged as a convicted impostor. In Lefevre's experiment with Louise Lateau he placed a leather glove upon one hand, tying and sealing it at the wrists; but it is easily to be seen why this test was not as thorough as that with the lead.

Another case of ecstasy with stigmatization is cited by Bourneville and Hammond from Magnus Huss of Stockholm—a servant-girl twenty-three years old who was subject to convulsions, and also to hemor-

¹ *British Medical Journal*, vol. i., 1871, p. 479.

rhages, which usually came on as the result of great emotional disturbance. In her case examination showed no cicatrices. The hemorrhages occurred from the scalp, the eyes, the face around the eyes, the left ear, and the stomach. Her menstruation went on regularly during the attacks: sometimes she had ecchymoses and apparent bruises on the left half of the body, the limbs of which were semi-paralyzed for short periods. The attacks occurred with convulsions and unconsciousness, which usually lasted about half an hour, and from which she awakened as if from a long sleep.

Autographic Women.

Certain peculiar phenomena have been described under the head of *femmes autographiques*, or the autographic women, and are worthy of note. Dujardin-Beaumetz¹ in a case of well-marked hysteria with loss of general sensibility reports that he was able to write or trace with a needle or pointed instrument on the skin. Within a space thus traced the skin was elevated in a white patch or plate. After some five minutes the line would show itself more and more in relief, until it attained from one and a half to two millimeters in thickness. It would remain from three to six, and sometimes twelve, hours. He varied the experiments in many ways, executing upon the skin designs, tables, and names of from ten to fifteen letters. He detected in the centre of some of the spaces traced a marked elevation of temperature, sometimes appreciable to the hand. This woman was known by the name of *femme dicke*, or the autographic woman.

Dujardin-Beaumetz held that the phenomena were vaso-motor. The red lines traced readily admit of this explanation. The white space in relief, however, was not so easily explained. He had observed among hysterical women, under the influence of pressure, irritation, or the application of magnets, the appearance of patches of urticaria. One of the common tricks of the Spiritualists is to have the name of a spirit that has been called up appear upon the bared arm of the medium. Among friends and private patients, and among the hysterical patients in the wards of the Philadelphia Hospital, I have successfully performed experiments similar to those reported by Dujardin-Beaumetz. Such phenomena are by no means confined to cases of hysteria. One of my most striking successes in an attempt at skin-writing was in the case of a male physician of a peculiarly clear and pale complexion. Certain peculiar conditions of the skin will allow this to be done with facility. The similarity of this class of phenomena to that of the stigmata will at once appear evident. Such phenomena occur among the hysterical with a tendency to vaso-motor deficiency of control.

Fasting Saints and Fasting Girls.

The wonderful saints who starved themselves or lived on sacramental bread are almost a multitude. Saint Joseph, Saint Catherine of Sienna,

¹ *Bull. et Mém. Société médicale de Hôpital de Paris*, 1880, 12, xvi. 197-202.

Saint Rose of Lima, Saint Collete, Saint Peter of Alcantara are of the number. In modern and even in recent times not a few of these cases have become widely known. Margaret Weiss, about whom a book was written in 1542, is said to have done without food and drink for three years. She suffered from pains and contractures. She passed neither urine nor feces; at least, such are the accounts which have come down to us.

Sarah Jacob, the Welsh fasting girl, has shared with Louise Lateau popular and medical notoriety. When about ten years old she suffered from various hysterical and hystero-epileptic symptoms. The quantity of food she took gradually dwindled; on October 10, 1867, it was said that she ceased to take any food whatever, and so continued till the day of her death, more than two years later. She had many visitors, pilgrims from far and near, who often left money or gifts. The vicar of her neighborhood came to believe in her, and an investigation was suggested. At one investigation, not very rigidly conducted, nothing was discovered. After a time she was visited by Fowler of London, who decided that the case was one of hysteria with simulation, probably associated with the power or habit of long fasting. Trained nurses were sent from Guy's Hospital to conduct the second watching. Under the watching the girl died, starved to death. The father was afterward condemned to imprisonment and hard labor for twelve months, the mother for six months. In Brooklyn a few years since one Molly Fancher, a similar case, attracted much attention, and was written about and commented upon by the press.

NEURASTHENIA.

By H. C. WOOD. M. D.

INTRODUCTION.—The term neurasthenia, signifying nervous weakness, and not rarely paraphrased by nervous exhaustion, indicates by its very derivation that it denotes not a distinct disease, but a condition of the body. The relations of the nervous system to the functions of organic and animal life are so intimate that almost all forms of exhaustion might well be discussed under the present heading. A further difficulty in attempting to decide the exact limitations of this article is to be found in the fact that hysteria, insanity, chorea, and various other nervous diseases are very closely connected with nervous exhaustion. Indeed, many of the cases which are considered by authorities as instances of neurasthenia would be more appropriately classed with one or other of the especial diseases. Thus, the nervous fears discussed in such detail by George M. Beard in his work upon neurasthenia plainly belong with the mono-maniacal insanities, and, although they usually are associated with nervous depression, may coexist with great physical and mental power.

Further, very many chronic diseases produce neurasthenia. It has not been many years since general debility was a common inscription upon records of diagnosis. In very many cases the general debility afflicted the diagnostic powers or zeal of the physician rather than the body of the patient, and it is to be feared that neurasthenia not rarely at present replaces it. Malarial poisoning, chronic Bright's disease, chronic diarrhœa, lithæmia, and various other affections may be readily overlooked, and patient and physician satisfied with the diagnosis of neurasthenia; indeed, in my own experience in a very considerable proportion of the cases which had been diagnosed as nervous exhaustion the patient was really suffering from definite disease.

The folly of attempting to make neurasthenia a distinct affection is strongly brought out whenever it is attempted to give sharp diagnostic differences between it and other diseases. As examples may be noted the flat contradictions which exist in the different diagnostic tables given in the elaborate work of the late George M. Beard.

It is necessary, therefore, in the outset, to recognize that neurasthenia is a bodily condition which is very frequently associated with various chronic disorders, or not rarely coexists with perverted functional activity of the nervous centres, which perverted nerve-functions may, however, exist independently of any perceptible neurasthenia, and are not simply the outcomes of the neurasthenia. Under these circumstances an apology

for devoting an article in this work to the consideration of neurasthenia may seem necessary to readers. The justification of the present discussion is to be found in the facts that neurasthenia often exists without the presence of definite disease, and that still more frequently it is a bodily condition which dominates in its therapeutic importance the manifestations of perverted functions, so that the patient is to be treated for it rather than for the disease with which it is associated.

ETIOLOGY.—There are various chronic diseases which may lead directly to nervous exhaustion. Neurasthenia may, moreover, be the result of disease which is long past; neglected diarrhœas, bleeding piles, and other affections with exhausting discharges, when they have been cured, may leave behind them conditions whose source and nature it is most important to recognize.

Overwork, excessive mental emotion, need only to be alluded to as capable of producing a pure neurasthenia. As Samuel Jackson was accustomed to say, in his lectures at the University of Pennsylvania thirty years ago, "Whenever the expenditure of nerve-force is greater than the daily income, physical bankruptcy sooner or later results." It is to be remembered that the nerve-capital of persons differs almost as widely as does their moneyed capital. There are numerous families many of whose members are neurasthenics from birth—*i. e.* who are born with less power of creating nervous energy than is necessary to meet the requirements of the ordinary duties of life. There is every grade of natural endowment between the most feeble person, scarcely able to produce more nervous energy than is necessary for breathing, eating, and drinking, and the organism that is capable of enduring incessant toil. The development of neurasthenia is therefore not so much the result of a strain which is absolutely great as of a strain which is excessive in its relations to the organism which has to bear it.

SYMPTOMS.—The onset of neurasthenia is always gradual, although at times the condition appears to develop with great suddenness. Under these circumstances, however, the explosion has been preceded by a long train of more or less overlooked phenomena: thus, in a case that just now occurs to me a gentleman had long suffered from the premonitory symptoms of neurasthenia, to which he had paid but little attention until he was one day seized with violent vertigo, accompanied by such prostration of strength that he had to be taken home from the street in a carriage. The symptoms vary very much according to the portion of the nervous system which is especially affected, and also to some extent according to the etiology of the attack. Nervous exhaustion may in the beginning affect the whole of the nervous system, or it may be at first purely local and coexist with general nervous strength. Many cases of spermatorrhœa are instances of the local form of neurasthenia, the sexual centres being primarily affected; but as in these cases, sooner or later, the whole of the nervous system becomes implicated, so in other forms of the disorder the exhaustion, at first local, finally, if neglected, implicates the whole organism. There are not rarely cases of brain exhaustion in which the symptoms are at first purely local. Almost always the cause of a local neurasthenia is excessive use of the part; thus, cerebral asthenia is usually the result of mental overwork, sexual asthenia of sexual excesses, etc. When to the intellectual fatigue is added the depressing effects

of excessive anxiety or allied emotions, the symptoms usually from the first are more general. The exhaustion may affect chiefly a single function of the brain. As an instance may be cited the case of a postal clerk now under my care, who has been accustomed to distribute five to eight thousand letters every day from a general mass into three hundred pigeon-holes representing as many post-office districts scattered over a large territory. As soon as the address is read there must be an instantaneous automatic recognition of the district to which the letter goes. It is at this place where, in the case now under consideration, the symptoms manifest themselves. Reading the address fails to produce immediate recognition of the locality to which the letter is to be assigned. Asked in what district such a post-office is, the clerk answers instantly, but seeing the address himself he hesitates, and sometimes balks so that he can distribute only about one-third as many letters as when in health. As in most cases of local nerve exhaustion, in this patient some evidences of general implication exist, there being decided disturbance of the sexual organs.

Another form of local neurasthenia which is frequently associated with brain exhaustion is that of writer's cramp. I have repeatedly seen it come on as the herald of a general breakdown; but under such circumstances the symptoms have usually not been those of typical writer's cramp: there have usually been not so much marked spasms as loss of power and distress in the arm on attempting to write.

In pure brain exhaustion loss of the disposition to work is usually the first symptom, the sufferer finding that it constantly requires a more and more painful effort of the will to perform the allotted task. The basis of this difficulty is largely loss of the power of fixing the attention, and this by and by is accompanied with weakness of the memory. Disturbances of sleep are frequent. Various abnormal sensations in the head are complained of. In most cases there is not absolute headache, but a feeling of weight or fulness or an indescribable distress, usually aggravated by mental effort.

It is true that in some cases of very dangerous brain-tire cerebation is performed with extraordinary vigor and ease; the power of work is for the time markedly increased, and even the quality of the product may be raised; the patient may even glory in a wild intellectual exaltation, a sense of mental power, with an almost uncontrollable brain activity. It is probable, however, that these cases are not instances of pure neurasthenia, but that there is an active congestion of the cortical gray matter. It is certain that they are very prone to end in serious organic brain trouble. In some cases of cerebral asthenia there are disturbances of the special senses, tinnitus aurium, flashes of light, and even the seeing of visions. Under these circumstances it is again probable that active congestion of the affected centres exists.

Severe cerebral neurasthenia may be associated with good spirits, but usually there is marked depression, and this perversion of function may finally go on to decided melancholy. The will-power, as all other functional activities of the brain, is prone to be weakened; morbid fears may finally develop themselves; and at last that which was at the beginning a simple brain exhaustion may end in hypochondriasis or insanity. In my own experience such ending is very rare unless there have been from the begin-

ning marked symptoms of hypochondriasis or melancholy; in other words, unless there be the inborn tendency to distinct mental disorders, cerebral neurasthenia rarely produces them, but in a person who inherits such tendency the brain exhaustion may become an exciting cause of insanity.

The symptoms of brain-tire may be very largely existing in the individual who still has muscular strength and is capable of enduring much physical labor; but in most cases, sooner or later, the more general symptoms of neurasthenia manifest themselves.

Amongst the earliest of these symptoms may be disorder of the special senses. For reasons which are not very evident it is the eye which is generally affected. Although existing deafness is often greatly intensified by the coming on of nervous exhaustion, I cannot remember ever to have seen severe deafness entirely neurasthenic. The nature of the optical trouble is to be recognized by the fact that vision is at first good, but fails when the eye is steadily used for a few minutes, although the organ is physically perfect. This weakness of the eye may long be the most troublesome manifestation of the disorder.

In some instances, before any loss of muscular strength is marked, vaso-motor weakness is prominent. Excessive blushing on the slightest provocation, great flushing of the face after the use of alcohol or other stomacheic irritant, waves of heat passing over the body, occasional pallors provoked by exertion or apparently causeless, and cold extremities, are some of the phenomena which mark the lack of power in the centres that control the blood-vessels. Closely allied to these disturbances are those of secretion. In my own experience the most marked of these is a tendency to night-sweats, but in some cases the hands, and more rarely the palms of the feet, are perpetually bathed in perspiration, which may be greatly increased by any emotional disturbance. In some patients there is a very great tendency to serous diarrhœa, which in its turn of course increases the nervous exhaustion.

In many neurasthenics the heart as well as the vaso-motor system sympathizes in the weakness, so that palpitation and shortness of breath not rarely follow even slight exertion: a more characteristic symptom is, however, a peculiar dropping of the heart's beat, which is to the patient at first very alarming, but which is entirely independent of any lesion of the heart itself. The true nature of this cardiac intermission is to be recognized by the existence of other symptoms of neurasthenia, and by the fact that it is not constant, and that it is very prone to follow eating or gastric irritation of any kind. Not rarely it is relieved at once by the belching up of wind. When tobacco has been very freely used the cardiac symptoms of neurasthenia usually come on very early, and may be very severe. Under these circumstances it is really a mixture of neurasthenia and tobacco-poisoning with which we have to deal.

The muscular strength may finally fail almost altogether. It is almost characteristic that the patient should be capable of much exertion under excitement, and should suffer from the results of such exercise not immediately, but after one or two days.

In many cases of neurasthenia atonic dyspepsia exists, but it is always a question for careful consideration how far a nervous condition is due to the dyspepsia and how far the dyspepsia is caused by the nervous condition.

Disturbances of sensation are common in neurasthenia, these disturbances taking the form in many instances of itchings or formication or other similar minor ills. Neuralgia is often severe and its attacks frequent, but I am convinced that something more than simple nervous exhaustion is responsible for its production. I believe that there is a neuralgic diathesis or temperament which is often associated with neurasthenia, but may exist without it, and which probably has, at least on many occasions, relations to a gouty ancestry. When such temperament exists the neuralgic attacks are greatly aggravated by the coming on of neurasthenia. Hyperæsthesia and anæsthesia mark the line where simple neurasthenia passes into hysteria. The same also is true of the peculiar tenderness over the spinal processes of the vertebræ, which is especially frequent in women, and is the chief symptom of the so-called spinal irritation or spinal anæmia—an affection which I believe to be a form of neurasthenia allied to hysteria.

In neurasthenia disturbances of the sexual organs are very common; in women great pain on menstruation, ovarian irritation, the so-called irritable uterus of Hodge, are closely connected with a general nerve weakness. In not a small proportion of the cases of uterine disorders which are often locally treated I believe the local disease is largely the expression of the general condition. It is well known that masturbation and sexual excess in the male may produce an exhaustion of the nerve-centres especially implicated and also a general nervous exhaustion. This is the common history of spermatorrhœa. It is no less true that a general neurasthenia may produce a local weakness of the sexual centres, with symptoms at least resembling those of spermatorrhœa—namely, great irritability of the sexual organs, with a practical impotence due to immediate seminal discharge whenever coition is attempted. I have certainly seen this condition result from excessive intellectual labor when there has been no sexual excess, and at a time when the muscular strength was still good. Such cases may, perhaps, be distinguished by the fact that unprovoked emissions are not nearly so apt to occur as in true spermatorrhœa.

TREATMENT.—The natural cure for neurasthenia is rest, and my own experience coincides with the logical inferences to be drawn from an etiological consideration of the subject—namely, that medicines are only of limited value, and unless very judiciously administered may readily do harm. Disturbing symptoms should be met and tonics may be used, especially strychnine and arsenic, but all drugs hold a secondary position in the relief of a pure neurasthenia. In using remedies the practitioner must be guided by general principles, and I shall not engage in any detailed consideration of the subject, but employ the space at my disposal with a discussion of rest.

When nervous exhaustion has been produced by over-use of any one organ or system of organs, absolute rest of such organ is a primary necessity. Thus, when there has been sexual excess absolute avoidance of use of the sexual organs must be enjoined, and in married Americans it is often essential to insist upon man and wife occupying distinct apartments¹ or even to separate them by a journey.

¹ Because in this country man and wife habitually occupy one bed. Sexual continence under these circumstances can only be obtained at the cost of a suppressed sexual excitement worse than moderate indulgence.

Again, in cases of brain-tire it is the brain which should be rested. To rest an overwearied, excited brain is often not an easy task. In attempting it the effort should be to obtain the following results: 1st. The removal of all cares, anxieties, and all brain-work, especially those of such character as have been connected with the breakdown. 2d. The maintenance of the interest of the patient, so that the past shall for the time being be forgotten, and the present not overweighted with irksomeness. 3d. Invigoration of the physical health of the whole body, and especially of the nervous system. In order to obtain the first of these measures of relief, isolation of some sort is essential; for the second mental occupation is usually required; for the third fresh air, exercise, or some substitute is to be superadded to abundant food and rest.

The proper method of meeting these indications varies greatly, not only with the varying physical conditions and idiosyncrasies of patients, but also with their diverse domestic and pecuniary relations. To give detailed directions for every case is impossible, and I shall therefore limit myself first to simple cases of brain-tire in which the muscular strength is preserved; second, to cases of profound general neurasthenia.

In brain-tire travel is usually recommended, and travel affords, when properly directed, separation from old cares and thoughts, a maintenance of interest by a succession of novel sights and experiences, and the physical stimulation of fresh air and exercise. In bad cases general travel is too stimulating, and ocean-voyaging is much better. Upon the ocean is to be found nothing provocative of thought, only complete isolation, fresh air, enjoyment if the patient be fond of the sea, and a sufficient exercise, especially if the sufferer in any large measure works in the management of a sailing vessel. Hence prolonged yachting affords in many cases our best method of relief. The isolation of the North Woods or any other large primeval wilderness may be complete, the air most fresh, and the exercise to be had also boundless, but at the same time controllable; the man may, according to his will, lie in his tent and be fed by his guide or be unceasingly active. If the life be agreeable to the sufferer, and sufficient care against undue exposure be exercised, the camp-cure is most efficient. European travel may serve almost equally well, provided hard journeying, sight-seeing, and even cities are avoided. The quiet of Switzerland or the Tyrol may bring restoration when the bustle of London and Paris might complete the ruin.

To those who cannot travel extensively the seashore, mountains, or lowlands of the United States are open, and the best way of meeting the indications in any individual case must be determined by a joint consultation between doctor and patient.

There are cases of neurasthenia in which the slightest exercise does harm, and in which even the unconscious effort of company and conversation is an injury. Between the extremely exhausted and the slightly brain-tired is every grade of case, and much tact is often required in properly regulating the treatment of the individual case.

It is only the most severe forms of neurasthenia which require the use of the so-called rest-cure. For such, however, it is a very valuable method of treatment. It finds its most brilliant application undoubtedly in neurasthenic women, but, more or less modified according to circumstances, it has a wide scope in the treatment of both sexes. When the bodily condition is

developed by prolonged lactation, nursing, grief, overwork, acute disease, or other temporary or removable cause, the rest-cure may give permanent relief; and even when the cause of the neurasthenia is largely inherited feebleness of constitution, it is a valuable though a more temporary remedy. This method of treatment has long been used in this city, and was especially dwelt upon in its general scope by Samuel Jackson, but in its modern form it has become a very valuable method of treatment, essentially different in its details from what it was formerly, and far more potent in its influence. To S. Weir Mitchell is due a great debt of gratitude, for by him has this improvement been made.

The principles of the rest-cure are absolute rest, forced feeding, and passive exercise. Absolute rest is often prescribed by the physician without being sufficiently definite and insisted upon. When it is desired to apply it most strictly, it should be clearly explained that the patient is not to be allowed to get out of bed even to pass urine or feces, not to feed himself or herself, or perform any act of the toilet whatsoever. The rest also must be for the mind as well as for the body, and it is essential that the patient be isolated. Separation from friends should especially be insisted upon in the case of women. It may be possible to separate a man in his own house completely from his daily cares, but a woman in her own house is in the midst of her daily business, and is like a man placed in the corner of his factory. In obstinately severe cases of neurasthenia complete and absolute isolation is a *sine qua non*, and especially when there is a decidedly hysterical element is it necessary to separate the patient entirely from her friends. Under these circumstances there must be a well-trained nurse who is personally agreeable to the patient. The confinement would be very irksome to any except the most exhausted patient were it not for the daily visit of those engaged in the treatment; to further provide against ennui the nurse should be a good reader, so that under the definite instructions of the physician she can occupy a certain portion of the time in reading to the patient.

In order to maintain the functions of the skin the patient should be well sponged in bed every morning after breakfast. A strong solution of salt, or, better, sea-brine, is to be preferred to simple water, and frequently it may be followed by the use of alcohol. In very feeble cases the alcohol may be employed alone. I have seen very good effects from momentarily rubbing each portion of the skin with ice just after the bathing.

The question of feeding is one of great importance, and requires the utmost care and attention from the physician. The end to be attained is to feed the patient as much as can be digested, but not to overdo and derange the digestion. Food should be given at intervals of two or three hours, and must be both light and nutritious. It should, at least at first, largely consist of milk, except in those rare cases in which that fluid does really disagree, and not merely is thought to do so. The milk should be skimmed or given in the form of koumiss. Beef and other concentrated meat-essences are valuable as stimulants, and may be used, especially as the basis of soups. Various farinaceous articles of food may be added to them, or if an egg be broken into the concentrated bouillon or beef-essence just as it ceases boiling a nutritious, and to many persons palatable, dish is obtained. When constipation exists, oatmeal

porridge, Graham bread, fresh or dried fruits may be allowed if readily digested by the patient. In order to give an idea of the general plan of the dietary, the following schedule of the daily life is given. Such a schedule should always be put into the hands of the nurse, who should be required to follow it strictly. It must be altered from day to day, so as not to weary the patient with monotony. It is especially important to remember that the diet must be carefully studied for each patient, and be adapted to the individual requirements of the case. Success will in a great measure depend upon the practical skill and tact of the physician in this adaptation :

8 A. M. Rolls or toast ; cocoa or weak coffee, or roasted wheat coffee ; beefsteak tenderloin or mutton chop.

9 A. M. Bathing.

11 A. M. Oatmeal porridge, with milk, or else a pint of koumiss.

12 M. Massage.

2 P. M. Dinner: Bouillon with or without egg ; beefsteak ; rice ; roast white potatoes ; dessert of bread pudding, blanc mange, or similar farinaceous article of diet.

4 P. M. Electricity.

5 P. M. Milk toast.

9 P. M. Half pint of skimmed milk or koumiss.

In many cases the patient at first can take very little food, and it is very frequently best to begin the treatment with an entirely liquid diet, giving milk every two hours, or using Liebig's raw-meat soup, with milk or plain farinaceous food, and only after a time gradually accustoming the patient to solid food. Not rarely a prolonged treatment by the so-called milk diet is of avail. The rest-cure is indeed largely based upon a careful regulation of the food ; but a full discussion of the various dietaries to be used would require a treatise upon dietetics.

Passive exercise is to be obtained by the use of electricity and massage, the object being to get the effects of exercise upon the nutrition and circulation without the expenditure of the patient's nerve-force. By the use of electricity muscular contractions are secured which simulate those which are voluntary and more or less thoroughly replace them. By the general application of the current to the whole body we probably affect the tone of all of the minute blood-vessels, and certainly in this or some other way stimulate the general nutrition, and, as has been shown by S. Weir Mitchell, for the time being elevate the bodily temperature.

The faradic current is alone used. It is applied in two ways : first, to the individual muscles ; second, to the whole body. The séances should be daily, the operator beginning at the hand or foot, and systematically faradizing each muscle of the extremities and trunk.

The slowly-interrupted current is generally preferable, but advantage is sometimes gained by varying the rapidity of the interruptions. The general rule is to select that current which produces most muscular contraction with the least pain. The poles should be applied successively to the motor points of the muscles, so as to contract each firmly and thoroughly. This process should occupy from thirty to forty minutes. The electrodes are then to be replaced by large sponges well dampened with salt water : one of these should be put at the nape of the neck and the other against the soles of the feet, and a rapidly-interrupted current, as

strong as the patient can bear, should be sent through the body for twenty minutes or half an hour. It is not necessary for the operator to remain during this time. In some cases the electrical programme may be varied so as to get a local stimulant action from the general current; thus, when digestion is enfeebled and the bowels costive for a portion of the time one of the sponges may be placed upon the epigastric region. In women when there is great abdominal and pelvic relaxation one pole may be placed high up in the vagina. I have seen old-standing prolapses cured in this way. Some electro-therapentists claim great advantage from galvanization of the cervic sympathetic ganglia, but I do not myself believe that they ever succeeded in reaching these ganglia with the current.

Massage, like electricity, affects greatly the peripheral circulation, empties the juice-channels, and gives tone to the muscular system. It must be clearly distinguished from rubbing of the skin. It consists in manipulations of such of the muscles as are not too deep to be reached, and of the cellular tissue: in order to lessen as much as may be the skin friction by these manipulations, it is often well to anoint the surface with cocoanut or other bland oil. As sold in the drug-stores, cocoanut oil is very often rancid, and at any time it is well substituted by the cheaper cottonseed oil. In practising massage it is essential to remember that the natural course of the venous blood and the juices of the cellular tissue is toward the centre of the body; therefore, all general movements should be practised in this direction.

The manipulations are percussion, rolling, kneading, and spiral. They consist of movements made with the pulpy ends of the fingers and thumbs, and spiral movements with the whole hand so folded as to adapt its palm to the limb. In percussion the strokes should be from the wrist, and should be quick and short. It is probably not possible, even by long strong strokes, to affect deep muscles. In the rolling manipulation the effort is to roll the individual muscles beneath the pulps of the fingers. This manipulation may be varied by pinching the muscles, not the skin, and kneading. In each case it is intermittent pressure upon the muscles which is aimed at. The circular movements are to be in opposite directions with both hands simultaneously, the limb being grasped by one hand a little above the other, and a spiral sweep made up the limb, the ball of the thumb and the palm of the hand resting upon the patient, and the pulpy parts of the thumb and the fingers grasping the limb. It is especially such motions as these which affect the circulation of the flesh-juices.

The length of time the patient is to be kept in bed and treated in the manner described varies of course with the individual case, but usually less than four weeks is not sufficient, and rarely are more than six weeks required. In getting up, the patient should begin by sitting up one or two hours a day, increasing daily, but not too rapidly, the time of being out of bed and the amount of exertion made. The electrical treatment should be gradually intermitted: in many cases massage twice a week seems to be of service even after the patient is about. In the going back to ordinary daily life great care is to be exercised to proportion the amount of exertion to the newly-obtained strength, so as not to lose what has been gained. In cases of natural or of long-standing acquired

severe neurasthenia the mode of life must be arranged to correspond with the small daily product of nervous energy.

In dismissing this subject I desire to caution against a routine employment of this so-called rest-cure, which might readily degenerate into a species of quackery ; and, again, to call attention to the widespread value of the principles which underlie it, and the importance of the physician applying those principles with endless modifications of detail.

SLEEP, AND ITS DISORDERS.

By HENRY M. LYMAN, A. M., M. D.

THE regularly-recurring incidence of natural sleep forms one of the most important subjects of physiological investigation. Occurring ordinarily at stated intervals connected with the diurnal revolution of the earth, it may for a time be postponed by an effort of the will, but an imperious necessity for repose finally overcomes all opposition, and the most untoward circumstances cannot then prevent the access of unconsciousness. Thus produced, the relation of cause and effect between weariness and sleep becomes very apparent. The refreshing influence of such repose points clearly to the restorative character of the physical processes that continue despite the suspension of consciousness; it also renders evident the final cause of that periodical interruption of activity which the brain experiences in common with every other living structure.

Careful observation of the manner in which sleep invades the body indicates that its evolution is not associated with a simultaneous suspension of every mode of nervous function. The sense of sight is the first to yield. The eyelids close and the muscles that support the head give way. The body seeks a recumbent position; quiet and seclusion are instinctively sought. The purely intellectual faculties are not yet depressed, and the reflex energies of the spinal cord are exalted. Soon, however, the other senses fail; hearing persists the longest of all. Released from the control of external impressions, the internal senses preserve their functions after a strangely-disordered fashion, dependent upon the progressive suspension of activity in the various cerebral organs. First the power of volition ceases; then the logical association of ideas comes to an end. Presently the reasoning faculties disappear, and judgment is suspended. We thus become no longer capable of surprise or astonishment at the vagaries of memory and imagination, the only mental faculties that remain in action. To their unrestrained function we owe the presentation in consciousness of the disorderly picture which we call a dream. During the early stages of this somnolent state we often remark the fact of dreaming, and an effort at attention may produce a partial awakening; but usually the subsidence of cerebral function is progressive and rapid. The fire of imagination fades; the field of consciousness becomes less and less vividly illuminated; the entire nervous apparatus yields to the advancing tide; and, finally, the dominion of sleep is fully confirmed.

During the act of awaking the order of sequences is reversed. From the end of the first hour of repose the depth of sleep, at first rapidly, then more gradually, diminishes.¹ Dreams disturb its quiet, mental activity increases, the power of volition revives; once more the individual is awake.

Sleep, then, is that condition of physiological repose in which the molecular movements of the brain are no longer fully and clearly projected upon the field of consciousness. This condition is normal, and must, consequently, be differentiated from all pathological states which produce its counterfeit by the more or less complete abolition of consciousness. This distinction becomes the more necessary because the presence of the common factor, unconsciousness, in the result has frequently led to the mistake of supposing a community of antecedents in the changes by which the passage from sensibility and consciousness to insensibility and unconsciousness is effected. It needs no argument to show that the insensibility of artificial anæsthesia is a very different thing from the unconscious condition which obtains during natural sleep. Between the stupor of intoxication and the healthful restoration of cerebral energy which accompanies genuine sleep there can be no rational comparison. It is therefore in the phenomena of syncope that the likeness of sleep has usually been sought. The well-known fact that a copious hemorrhage can speedily develop a condition of muscular relaxation, insensibility, and unconsciousness has led certain observers to the belief that natural sleep is, after all, only a species of physiological syncope. The antecedent conditions of syncope are so different from the prodromata of sleep that it is difficult to see how either state can be properly likened to the other. The bloodless condition of the brain which occasions syncope is always the result of pathological or accidental causes, and is not identical with the comparatively insignificant reduction of blood-pressure which may be observed in the brain of the healthful sleeper. It is, moreover, worthy of note that sleep is the normal condition of the unborn child, despite the fact that the growing brain receives a richer supply of oxygenated blood than the trunk and the lower limbs—a state of the circulation quite unlike that of syncope.

Fully impressed by the force of such considerations, certain physiologists² have reasoned from the analogies suggested by the results of muscular fatigue, and have imagined an hypothesis accounting for the occurrence of sleep by a supposed loading of the cerebral tissues with the acid products of their own disassimilation during wakeful activity. The acid reaction of the brain and of the nerves after exertion suggested the probability that an excessive presence of lactic acid and its sodic compounds might be the real cause of cerebral torpor and sleep. Could the hypothesis be proved, ordinary sleep would take its place in the anæsthetic category and sodic lactate should be the very best of hypnotic agents. Unfortunately for this doctrine, the administration of the lactates has yielded only the most contradictory and unsatisfactory results. It, more-

over, furnishes no explanation of intra-uterine sleep nor of the invincible stupefaction produced by cold.

Far more comprehensive is the hypothesis of Pflüger.¹ According to this view, the cortical tissues of the brain are recruited by the assimilation of nutrient substances derived from the blood. By this process oxygen is stored up in chemical combination, forming explosive compounds whose precise composition is not fully understood. Under the influence of the various nervous stimulations that reach the brain these unstable compounds break up into simple forms. The motion thus liberated by these explosions is, in some way at present utterly unintelligible to us, projected into the field of consciousness where the mind dwells, and we are thus brought into conscious relation with the external world. That the capacity for thus signalling across the gulf which separates matter from mind is the result of a certain perfection and complexity of material structure is rendered probable by the utter failure of the infracortical organs of man to impress the conscious intelligence by any amount of independent activity. It is also indicated by the unconscious sleep of the rudimentary foetal brain and by the brevity of the intervals of wakefulness which mark the life of the new-born babe. That this capacity is dependent upon the mobility of the atoms of the brain is shown by the speedy cessation of intelligence which follows great reduction of temperature, as in hibernation or during exposure to severe frost. That its exercise is largely dependent upon the activity of the senses is proved by the effects of interference with their function. A recent observation, recorded by Strümpell,² is very significant in this connection: A young man had lost all power of sensation excepting through the right eye and the left ear. A bandage over the eye and a plug in the ear arrested all communication between his brain and the external world. Thus imprisoned within himself, he gave utterance to an expression of surprise, and sought in vain, by clapping his hands, to arouse the sense of hearing. At the end of two or three minutes these efforts ceased; respiration and pulsation were deepened and retarded, and removal of the bandage exhibited the patient with his eyes closed in genuine sleep.

The dependence of the waking state upon the presence and functional activity of a sufficient quantity of a peculiarly unstable form of protoplasm in the brain is an hypothesis which presents no great difficulty of comprehension. But how may we explain the passage from the vivacity of that waking state into the inactivity of sleep? I have elsewhere³ discussed the manner in which artificial sleep is produced by impregnation of the brain with anæsthetic substances, and the same general line of argument may be extended to cover the action of every stupefying agent with which the blood may become overcharged. Could the hypothesis of Obersteiner and Preyer be accepted, it would be an easy matter to explain the advent of sleep when it gradually supervenes; but we cannot thus explain the rapid and intentional passage from wide-awakefulness into the profoundest sleep, such as becomes a matter of habitual experience with sailors and with others who have formed the habit of going at once

¹ "Theorie des Schlafes," *Arch. f. d. Ges. Physiol.*, x. 468.

³ *Artificial Anæsthesia and Anæsthetics*, pp. 15-17.

to sleep at regularly-recurring periods of time. Certain writers have endeavored to account for this fact by imagining a special mechanism at the base of the brain (choroid plexuses of the fourth ventricle, etc.), by means of which the current of blood through the brain may be voluntarily diminished, with a consequent arrest of conscious activity. But, still adhering to the hypothesis of Pflüger, we shall find a clearer explanation of the facts by considering the phenomena connected with the succession of impressions upon the organs of sense. It has been ascertained¹ that such impressions must persist for a certain measurable length of time in order to excite conscious perception. A sound must be prolonged for at least $0.14''$, a ray of light must agitate the retina for $0.188''$ – $0.2''$, ordinary contact with the surface of the body must continue during $0.13''$ – $0.18''$, in order to produce any knowledge of sound and light and common sensation. For the simplest act of perception $0.02''$ – $0.04''$ are necessary. It is therefore perfectly reasonable to suppose that when the explosive material of the brain has been sufficiently reduced in quantity and quality by prolonged cerebral effort, the impression of sense may no longer suffice to excite in the cortical substance vibrations of sufficient length, or following each other in sufficiently rapid succession, to sustain the conscious state. The cortex of the brain may then be likened to the surface of a body of water into which bubbles of soluble gas are introduced from below. When the bubbles are large and succeed each other rapidly, the surface is maintained in a state of continual effervescence. But if the size of the bubbles be diminished or if the solvent capacity of the liquid be increased, its surface will become almost, if not quite, perfectly tranquil. In some such way, without any great amount of error, may we picture forth the molecular changes that determine the advent of sleep.

Returning now to the subject of the rapid induction of sleep, we find that it usually occurs among people who lead an active life in the open air, like children and laborers, and are perhaps compelled to endure frequent interruptions of their rest. The sailor who is trained to sleep and to work in rapidly-successive periods of time—four hours on deck and four hours below—has virtually become transformed by this habit into a denizen of a planet where the days and the nights are each but four hours long. His functions become accommodated to this condition; his nervous organs store up in sleep a supply of protoplasm sufficient only for an active period of four or five hours, so that when his watch on deck is ended he is in a state as well qualified for sleep as that of a laborer on shore at the end of a day of twelve or fifteen hours. Moreover, the majority of those who manifest the ability thus to fall asleep are individuals whose waking life is almost entirely sustained by their external perceptions. So soon, therefore, as such excitants are shut out by closing the eyes and by securing shelter against the sounds and impressions of the air, comparatively little remains for the production of ordinary consciousness, and sleep readily supervenes, especially if the excitable matter of the brain has been already depleted by active exertion.

It is well known that a predisposition to sleep may be very quickly induced by extraordinary expenditures of force; witness the effect of the venereal act and the consequences of an epileptic fit. That analogous

¹ Carpenter's *Physiology*, 8th ed., p. 852.

predispositions may indeed be very rapidly developed by modifications of cerebral circulation is shown by the sudden reduction of cerebral excitability during the act of fainting. But this does not prove that cerebral anæmia should be elevated to the rank of the principal cause of natural sleep. In all such cases the nervous process is the primary factor and the direct cause of change in the circulation.¹ The character of these changes has been admirably illustrated by the observations of Mosso.² By the aid of the plethysmograph this experimenter was enabled to compare the state of the circulation in the human brain, laid bare by erosion of the cranial bones, with the movement of the blood in other portions of the body. The occurrence of sleep caused a diminution in the number of respirations and a fall of six or eight beats in the pulse. The volume of the brain and its temperature were at the same time slightly reduced through the diversion of a portion of the blood-current to other regions of the body. If during sleep a ray of light was allowed to fall upon the eyelids, or if any organ of sense was moderately excited without waking the patient, his respiration was at once accelerated, the heart began to beat more frequently, and the blood flowed more copiously into the brain. Similar incidents accompanied the act of dreaming. The renewal of complete consciousness was followed by an immediate increase in the activity of the intracranial circulation.

In all these variations it is worthy of note that the nervous impression was the primary event. The changes of blood-pressure and circulation were invariably secondary to the excitement of nerve-tissue. Sleep, therefore, is the cause, rather than the consequence, of the so-called cerebral anæmia which obtains in the substance of the brain during repose. This condition of anæmia is nothing more than the relatively lower state of circulation which may be discovered in every organ of the body during periods of inactivity. Every impression upon the sensory structures of the brain occasions a corresponding liberation of motion in those structures. The movement thus initiated arouses the vaso-dilator nerves of the cerebral vessels and excites the vaso-constrictor nerves of all other portions of the vascular apparatus. Hence the superior vascularity of the brain so long as the organs of sense are fresh and receptive; hence the diminishing vascularity of the brain as its tissues become exhausted and unexcitable; hence the unequal and variable vascularity of different departments of the brain as sleep becomes more or less profound. These modifications of the brain and of its circulation are well illustrated by the effects of a moderate degree of cold applied to the cutaneous nerves of the body, as not infrequently happens when the night air grows cool toward morning. Such moderate refrigeration of the skin excites its sensitive nerves, which transmit their irritation to the brain. The excitement of this organ causes dilatation of its vessels, with increased irritability of the cortex, vigorous projection into the field of consciousness, and the consequent occurrence of dreams denoting imperfect slumber or even complete awakening. The remedy consists in the application of gentle heat to the surface of the body. By this means the transmission of peripheral irritation is checked; the brain becomes tranquil; sleep super-

¹ W. T. Belfield, "Ueber depressorische Reflexe erzeugt durch Schleimhautreizung," *Du-Bois Reymond's Archiv*, 1882, p. 298.

² *Ueber den Kreislauf des Blutes im menschlichen Gehirn*, Leipzig, 1881.

venes. A similar wakefulness is in like manner produced by unusual heat. The remedy here consists in the employment of measures calculated to reduce the temperature of the skin to the normal degree. Sometimes wakefulness is maintained by some less general irritant. The feet alone may be cold, either because of previous refrigeration or because of local hyperæmia occurring elsewhere in an anæmic subject. There, again, equalization of the circulation—that is, the removal of cerebro-spinal irritation—may be all-sufficient to procure sleep. Noteworthy also is the tranquillizing effect of foot-baths or of the wet sheet in many cases of cerebral excitement and wakefulness. In like manner, that form of sleeplessness which often follows intense mental activity may generally be obviated by a light supper just before going to bed. Activity of the stomach is thus substituted for activity of the brain, and the consequent diversion of blood is sufficient to reduce the production of excitable matter in the brain to a point that permits the occurrence of sleep. A morbid exaggeration of this process is sometimes witnessed in the soporose condition that accompanies digestion in patients whose blood has been reduced by hemorrhage or by disease. In such cases the nutrition of the brain proceeds at so slow and imperfect a rate that any considerable diversion of blood toward other organs produces a syncopal slumber which resembles normal sleep only by the fact of unconsciousness. If, however, food be taken in excessive quantity or of irritable quality, the consequent indigestion will produce nervous excitement, reaching perhaps to the brain, and preventing sleep.

Dreams.

The most interesting question regarding sleep concerns the condition of the mind during repose. We know that while the body is awake the mind is always active: does this activity entirely cease during the period of sleep? The phenomena of certain varieties of trance indicate that the mere semblance of death is not incompatible with great mental activity. In like manner, the phenomena of dreams serve to prove that various intellectual processes, such as memory, imagination, attention, emotion, and even volition, may still be exercised while every external avenue of special sense is closed by sleep. The result of the exercise of mental activity under such conditions constitutes a dream. The fact that observers who have made trial in their own persons have always found themselves engaged with the details of a dream when suddenly awakened from deep sleep has been supposed to afford valuable proof of the proposition that the mind is never wholly inactive during the deepest sleep. To say nothing of the significance of certain somnambulist states (double consciousness), in which intelligence evidently exists for a long period of time without leaving any subsequent trace in memory, the mere fact that we remember very few of the events that occupy the mind in dreams cannot be urged against the doctrine of continuous mental action, for we remember very few of the images and ideas that have stirred the depths of consciousness during the waking state. Our recollection of dreams is exceedingly variable. Sometimes we retain in memory all the events of a long and complicated vision, but usually, though entranced by the vivid

beauty of the spectacle that unrolls its splendor before the eye of the mind in sleep, and though the intensity of its seeming action may be sufficient to awaken the dreamer, who recalls each incident as he reviews the picture during the first waking moments, the impression soon fades, and the coming day finds him incapable of reproducing a single scene from the nocturnal drama.

The space allotted to this article will not admit a full discussion of the physiology of dreams. A brief reference to the definition of sleep must suffice to indicate what is signified by the process. Sleep does not wholly arrest the functions of the brain. A certain amount of projection into the field of consciousness seems to continue even during the most perfect repose, and the ideas thus aroused form the material of our dreams. Our waking hours are occupied with the ideas and with the associated trains of thought that are presented in consciousness through the action of our several senses. As a consequence of the harmonious function of these senses, correcting and supplementing each other, a continuous process of logical thought is maintained. But along with the procession of ideas which are distinctly conceived by the mind, the field of consciousness is also invaded by a cloud of half-formed perceptions that are too imperfect and too fleeting to occupy the attention. As in the act of sight, though the periphery of the visual field is clouded with a whole world of objects dimly perceived without arresting particular attention, the centre of that field alone presents a clear image before the brain, so the eye of the mind perceives clearly only a few of the impressions which enter the sphere of consciousness. These neglected perceptions, however, are none the less the result of abiding impressions graven in the substance of the brain, from which, through the action of memory, they may at any favorable opportunity re-enter consciousness. It is well known that a suspension of the functions of any portion of the nervous apparatus tends to increase the energy of the remaining organs ; consequently, it becomes highly probable that with the arrest of external perception in sleep the activity of certain portions of the brain must be considerably exalted, so that the impressions which they have previously registered may now more clearly reach the seat of consciousness. The probability of this hypothesis is greatly strengthened by numerous facts that lie open to observation. During the first moments that succeed the closing of the eyes mental activity and the power of attention are not diminished, but are rather increased. As the controlling influence of the cerebrum is withdrawn the reflex energy of the spinal cord becomes temporarily exalted. Witness the paroxysms of cough that sometimes harass a sleeping child who has scarcely coughed at all during his waking hours. Witness the voiding of urine in the bed by nervous children during the early hours of sleep. Witness the phenomena of night-terrors, which always occur at the time of night when sleep should be most tranquil.

It appears, therefore, that the harmonious activity of all parts of the nervous system is indispensable to the highest exercise of the conscious mind. Healthy intellectual life is the perfectly-balanced outcome of the complex polygon of forces which has its seat within the brain. But the suppression of certain lines of this polygon does not suppress life, nor does it necessarily destroy consciousness. It only occasions a redistribution of force and a proportionate narrowing of the stream of related

ideas. Since the suppression just mentioned is not an absolute quantity, but a variable factor, the polygon of forces in the brain and the corresponding succession of ideas in consciousness must necessarily be in a state of continual change. Accordingly, our dreams are as variable as the clouds that drift upon the currents of the air. As on a hot day in summer, when the steady equatorial draught has ceased to guide the wind, we may observe all manner of local tides in the masses of vapor which arise from the earth, so in sleep, when the guiding influence of the senses is withdrawn from the brain, the ideas that still arise are chiefly dependent upon its automatic and reflex action for their origin and association. Undisturbed by impulses from the external world, the brain seems then more sensitive to impressions that originate within the body. An overloaded stomach, an enfeebled heart, a turgid sexual apparatus, or an irritable nervous ganglion may become the source of irregular and uncompensated movements which may invade the cerebral cortex, and may there set in motion a whole battery of mechanisms whose influence upon consciousness would be quite unnoticed were the external senses in full operation.

Night-Terrors.

The preceding argument will render it easy to comprehend the phenomena of night-terrors. These are commonly observed in young children of a highly nervous temperament before the conclusion of their second dentition. The subjects of the disorder are generally of neurotic descent. Insanity, hysteria, neurasthenia, epilepsy, chorea, and nervous dyspepsia are often discovered among their near relatives. Not infrequently they have been or will become themselves choreic.

The attack is often preceded by symptoms of indigestion, but it may result simply from the commotion of a brain wearied by the excitement and effort of the previous day. The little patient starts up out of an apparently sound sleep crying with alarm, calling for his mother, and staring wildly with every possible expression of terror. Sometimes he springs from his couch and runs headlong into a corner or seeks to hide under the bed, as if escaping from some frightful object. The eyes are open, tears flow, perspiration covers the skin, there is the greatest excitement, and the little one, convulsively clinging to its parent, will not be quieted. Only after fifteen or twenty minutes, as tranquillity gradually returns, does the child seem to recover the power of recognizing his friends. Presently, however, he lies down and falls quickly asleep, waking in the morning without the slightest recollection of the unpleasant event.

Such paroxysms occur during the early part of the night, one or two hours after the child has been put to bed, just at the time when, according to the previously-quoted experiments of Kohlshütter, sleep is passing from its maximum intensity to a lesser degree of depth. This, then, is the time when the controlling power of the sensory apparatus over other portions of the nervous system has already reached its minimum. The spinal centres and those intracranial ganglia which do not share in the full measure of this repose are therefore in a condition of relative exalta-

tion. Disturbances of internal organs consequently produce inordinate excitement of these waking portions of the nervous apparatus. The morbid quality of this excitement is attested both by the history of the patient and by the fact that it does not arouse the whole brain. The distribution of motion in the cerebrum is impeded, so that certain portions of the organ remain asleep while other regions are thrown into a state of tumultuous uproar. Disconnection of these different organs of the nervous system, by withdrawing particular portions from the inhibitory influence of the remaining parts, gives opportunity for violent explosions of nervous force analogous to the convulsions of a headless fowl or to the course of an epileptic paroxysm. Now, in sleep, in somnambulism, in hypnotism, in delirium, in certain stages of intoxication with alcohol or with narcotics, such ungearing of the different nervous ganglia is more or less completely effected. In narcotic and anæsthetic sleep besides the disassociation of ganglia there is paresis of the nervous molecules; hence the phenomena soon merge into insensibility and coma. But in natural sleep, in somnambulism, or in hypnotism there is no toxic paresis; hence the dissociated portions of the brain and nervous system, if aroused, are in a physiological condition to dispense great stores of force. Hence the vividness of certain dreams and the astonishing vigor of particular nervous functions in somnambulism and hypnotism.

Somnambulism.

The phenomena of night-terrors constitute merely a special form of somnambulism, a condition of which the mechanism, so far as the present state of cerebral physiology will permit, has been already suggested. The affection should not be ranked by itself as a particular variety of disease, but should rather be considered a violent perturbation in the cerebral organs of a neurotic subject during the period of sleep. In ordinary dreaming the muscular apparatus usually remains passive, even though the dream be a nightmare or an incubus of the most terrifying character. But when the desires and the emotions are powerfully addressed by the dream, a certain amount of muscular movement may ensue, as when a dog barks in his sleep, or when a child laughs upon his nurse's lap, or when a weary soldier marches on though overpowered by sleep. One night, when parched with thirst during a voyage at sea,¹ I saw in sleep a sparkling fountain, by the side of which appeared a young girl holding out a cup of cold water. Awakened by the excitement, I found myself sitting up in bed with my right arm extended in the direction of the tantalizing vision: my dream had merged itself in action. In like manner, the victim of night-terrors not only moves his body, but gives vocal expression of his feeling of apprehension and alarm. In like manner, projecting his dream into action, a sleep-walker may arise from his bed; he climbs out of the window and descends to the ground, executing all manner of complicated and dangerous movements; he walks long distances, and finally returns to his couch without waking. In the morning no recollection of the event of the night survives. Again, the movement

¹ A proclivity to dreaming has often been remarked among the consequences of partial starvation.

may be less locomotive in its character. The intellectual faculties chiefly may be aroused, and then only such movements are executed as may be necessary to give expression to the mental process.

Such, then, are the principal characteristics of somnambulism, a state in which dreams are supplemented by more or less complete and appropriate action, ordinarily without subsequent recollection of either dream or action.

The somnambulistic dream generally occurs during or soon after the period of deepest sleep, when the influences of the external world are largely suppressed. Released from the control of its sensory portion, the remainder of the brain awakes and becomes aroused to a condition of functional exaltation. No longer distracted by the recollection of the special senses, the attention is concentrated upon the hallucinations which constitute the dream. In the simpler forms of noctambulism only the automatic locomotive apparatus is awakened, and the sleeper moves in accordance with the impressions derived from habit aided by exaltation of the muscular sense. But in some of the more complicated cases a certain amount of special sensibility seems to exist. The patient is capable of exercising just that amount of sensation which is necessary to accomplish his purpose, though blind and deaf and insensible to every other impression. The more complete the waking of the organs of sense, the closer the resemblance to the condition of ecstasy in which cerebral exaltation is the prominent feature. Accordingly, it sometimes happens that the somnambulist can recall the events of his paroxysm.¹ In such cases the power of recollection is due to the same conditions that control the recollection of our ordinary dreams. We remember very imperfectly, if at all, the dreams that occur during sound sleep, but the visions with which sleep sometimes commences (hypnagogic hallucinations) and those that occupy the period of morning slumber are very easily reviewed in memory, because they are associated with impressions directly derived from the partially-waking organs of sense. Such dreams are therefore chiefly recalled through their association with the train of our waking thoughts. But the dreams of somnambulism and the dreams of night-terrors, and all other visions during profound sleep, are as completely as possible cut off from all connection with the mental activities which arise directly from the action of the senses. By reason of such isolation the ordinary association of ideas affords no help to the memory, and the dream remains in the limbo of oblivion.

Alfred Maury expresses the opinion² that the principal cause of forgetfulness of the events of somnambulism consists in the exhaustion of the cerebral elements through the intensity of the excitement to which they are subjected during the paroxysm. Doubtless this in certain cases may contribute to the loss of memory, but it should be remembered that the excitement may be relative rather than absolute. Certain elements wake while others are asleep, and the waking cells may be aroused to a degree far in excess of what is usual during the sleep of the brain without attaining to the level of their diurnal activity. The mind, undisturbed by external impressions, gives its attention to the activity of these waking organs, and a dream with all its consequences, somnambulist or otherwise, is the result. In other words, the plane of consciousness, so to speak, is lowered

¹ A. Bertrand, *Traité du Somnambulisme*, p. 80.

² *Le Sommeil et les Rêves*, p. 226.

during sleep to the level of these molecular vibrations. But when the whole brain is again awakened after sleep the residual vibrations of those elements which yielded the physical basis of the dream, and which, had they occurred during the waking state, might have persisted with energy sufficient to furnish a groundwork for recollection of the ideas which they had originally suggested, are no longer sufficiently energetic to be felt in consciousness. Recollection of mental states thus generated must necessarily be impossible so long as the mind is dependent upon the brain as its register of events. Sometimes, however, the somnambulist, who while awake had forgotten all the incidents of his somnambulist experience, can remember in a subsequent paroxysm all that occurred during the preceding attack. Facts of this kind have been observed in the waking life of certain hysterical persons,¹ but the apparent interruptions of their personality attach to the waking state, while in ordinary somnambulism it is only in sleep that the alternations of memory and forgetfulness occur. A similar recollection of previous visions is sometimes experienced in dreams, showing the close relation that subsists between the dreams of sleep and of somnambulism. The bond of association between these events thus isolated in time must be sought in a renewal of like conditions of the brain during the successive periods of somnambulist exaltation. We must suppose that the molecules which were in a state of functional excitement during the first paroxysm are again aroused in like manner after a period of waking quiescence. If, during sleep, their movements, though of an exalted character, have only just sufficed to arouse consciousness in the form of a dream, it would not be probable that during the phase of comparative inactivity which supervenes when the whole brain is awake their residual motion could disturb the sphere of consciousness. Hence the time occupied by their somnambulist vigor must remain a blank in memory during the waking state. But when the original state of exaltation has been reproduced by a second period of disorder, if the same molecular movements be in any way renewed, the conditions of memory are fulfilled; consciousness is once more aroused as before, and the patient remembers the dream or the events of the previous attack.

Artificial Somnambulism, or Hypnotism.

The phenomena which have now been passed in review are of apparently spontaneous origin during the ordinary period of sleep. But from the remotest antiquity it has been known that certain persons may be thrown into an artificial sleep which closely resembles the condition of the somnambulist. During the persistence of this state certain portions of the nervous system become utterly insensible to external impressions, while other portions acquire an exalted degree of sensibility. The subject of the experiment can then by special methods be placed in such relations with other waking individuals that his surviving sensations, mental processes, and physical actions shall be no longer regulated by his own volition, but by the will of another. Such susceptibility is not common to all persons. About 20 per cent. of the ordinary population is, by some observers, considered capable of experiencing this condition. Heiden-

¹ *Annales Medico-psychologiques*, 5e Série, t. xvi. p. 5, 1876.

hain,¹ experimenting upon a class of medical students, found only one in twelve who was thus susceptible. Charcot, whose field of observation covers the inmates of the Salpêtrière Hospital, finds the best exemplars of the hypnotic state among the hystero-epileptic females in that asylum. To these experimenters we are largely indebted for the most extended scientific observation of the phenomena of hypnotism, giving precision and publicity to the knowledge of facts which, though equally well known within a narrow circle of investigation² during the earlier decades of the present century, have been compelled to await the development of cerebral physiology before their full significance could become apparent to the mass of the medical profession.

The antecedent condition most favorable to the production of the hypnotic state is a highly unstable constitution of the nervous system. For this reason the larger number of qualified subjects is furnished by the female sex, especially by those who possess the hysterical temperament. Frequent repetition of hypnotic exercises renders the subject still more susceptible. Heidenhain was at first inclined to believe that such experiences were not prejudicial to the health of the subject, but the observation of Harting in the University of Utrecht, and of Milne-Edwards in Paris,³ have demonstrated danger to the health of animals subjected to similar experiments. It is easy to discover, in the various clinical narratives published by Charcot and his pupils,⁴ evidence that hysterical patients often manifest considerable exhaustion after hypnotic exhibitions; consequently, it cannot be admitted that the practice is devoid of risk to the health of the individual.

Numerous methods of inducing the hypnotic state have been employed by different experimenters. The greater number consist in modifications of the sensory impulses derived from the periphery of the body. Gentle pressure upon the closed eyelids; convergence of the axes of the eyeballs upon some object nearer than the proper focal distance of the eyes; fatigue of the retina by gazing upon any brilliant or luminous object; monotonous excitation or sudden surprise of the auditory nerve; various impressions through gentle friction or pressure upon different regions of the body,—all these are capable of inducing hypnotic sleep. An appeal to the imagination, or even the mere attempt to abnegate the possibility of vigorous thought by confining the attention to the most trivial of things, sometimes suffices to produce the desired phenomenon. Thus, Heidenhain put one of his students to sleep at a distance by merely informing him beforehand that at a certain hour he would hypnotize him in his absence. The state of ecstatic meditation into which the monks of Mount Athos plunged themselves by the practice of omphaloscopy affords an illustration of the hypnotic effects of concentrated attention.

The duration of hypnotic sleep is exceedingly variable, but if left to himself the patient usually wakes spontaneously, without recollection of anything that has happened. If it be desirable to awaken him before the natural termination of the paroxysm, consciousness can be restored by almost any sudden and energetic appeal to the senses, such as an

electric shock, a sudden illumination of the eye with vivid light, or a sharp puff of air upon the face.

According to Charcot,¹ three principal types may be remarked among the hysterical subjects upon whom he experimented: (1) the cataleptic, (2) the lethargic, and (3) the somnambule. Of these, the first may be developed primarily by any abrupt and powerful impression upon an organ of sense, as a bright light or a loud noise (gong). Fixing the eyes upon some object may produce the same result. Dumontpallier, for example, has reported the case of a young woman² who accidentally hypnotized herself by gazing at her own image in the mirror before which she was dressing her hair. The cataleptic state may also be secondarily induced by merely opening the eyes of a patient in whom a condition of hypnotic lethargy has been previously developed. If only one eye is thus opened, the corresponding side of the body alone becomes cataleptic. Closing the eyes causes the disappearance of this symptom, with complete restoration of the purely lethargic state. During the cataleptic condition the several tendinous reflexes disappear, neuromuscular hyperexcitability ceases; the skin becomes insensible, but the special senses, particularly those of sight and hearing, maintain a partial activity. In this state the senses may become avenues of suggestion for the production of muscular movements, but if left to themselves the limbs remain motionless.

The lethargic state may be induced by simply closing the eyes of the patient or by causing him to fix his gaze upon some definite object. The paroxysm begins with a deep inspiration causing a peculiar laryngeal sound, followed by the appearance of a little foam on the lips. The eyelids are either wholly or partially closed, and are in a state of continual tremulous motion. The eyeballs are generally turned upward and inward. The muscles are completely relaxed. The tendinous reflexes are exaggerated; pressure over a muscle or upon a nerve arouses a peculiar contraction of synergic muscles and of groups of muscles which are supplied by the excited nerve-trunk. The facial muscles, however, do not thus become contracted: they merely contract during the application of the stimulus. If the lethargic patient be rendered cataleptic by opening the eyes, these contractions persist even after awaking, and they can only be dispelled by renewing the lethargic state before resorting to pressure upon the antagonistic muscles—a process by which the contractures peculiar to this species of lethargy may always be annulled. By the approach of a magnet to a contracted limb the phenomenon may be completely transferred to the corresponding muscles upon the opposite side of the body. If upon a limb of a lethargic patient who has been rendered cataleptic by opening the eyes an Esmarch's band be applied, pressure over the bloodless muscles excites no contracture until the band is removed. A contracture is then developed, and it may even be transferred to the opposite limb by the approach of a magnet. To this phenomenon has been applied the term latent contracture.

The extraordinary muscular excitability manifested by these hysterical hypnotics is further illustrated by an observation recorded by Dumontpallier.³ If one end of a caoutchouc tube one centimeter in diameter and

¹ *Le Progrès médical*, Feb. 18, 1882, p. 124.

² *Ibid.*, March 25, 1882, p. 223.

³ *Ibid.*, Jan. 14, 1882, p. 25.

five or six meters in length be applied over a muscle in the leg, and if the other end be in like manner connected with a watch, every movement of the second hand will be followed by a slight contraction in the muscle. The same result follows connection with the wire of a telephone, and if a microphone be introduced into the circuit the incidence of a ray of artificial light upon the instrument, or even its glancing reflection from the eye, will arouse a responsive muscular contraction. Charcot has sometimes observed muscular contractions upon the opposite side of the body when a mild galvanic current was applied to the parietal surface of the head. During the manifestation of muscular hyperexcitability there is complete analgesia, but the senses of sight and hearing seem to preserve some degree of activity. The patient, however, does not manifest any susceptibility to influence by suggestion.

The somnambulist state may be directly induced by fixed attention with the eyes, by feeble and monotonous excitation of the senses, and by various other methods of an analogous character. This forms the most common variety of the hypnotic condition. It may very easily supervene during either the lethargic or the cataleptic state as a consequence of pressure or gentle friction upon the top of the head. Thus, Heidenhain caused muscular paralysis by rubbing the scalp. Unilateral friction of the same surface produced paralysis of the opposite side of the body without notable affection of consciousness. The eye and the eyelids behave as in the lethargic state. The patient seems asleep, but there is less muscular relaxation than in hypnotic lethargy. There is no exaggeration of the tendinous reflexes, and muscular hyperexcitability is absent. But by lightly touching or breathing upon the surface of a limb its muscles may be thrown into a condition of rigidity which differs from the contracture of the lethargic state in the fact that it does not yield to excitation of the antagonistic muscles, though yielding readily to a sudden repetition of the same form of excitement by which it was originally produced. From the immobility of the cataleptic state it also differs by a greater degree of resistance to passive motion. Though analgesia may be perfectly developed in this state, there is generally an exalted condition of certain forms of cutaneous sensibility and of the muscular sense. Strange perversions of other special senses are sometimes remarked. Cohn¹ discovered that a patient who was naturally color-blind "when unilaterally hypnotized was able to distinguish colors which were otherwise undistinguishable." Conversely, when the cataleptic state is induced the eye becomes incapable of discerning colors. Spasm of accommodation is also present, and is one of the earliest demonstrable symptoms of the hypnotic condition.

These remarkable exaggerations and perversions of special sensibility have been the cause of much scepticism on the one hand regarding the verity of the phenomena of hypnotism, and of much credulity on the other, extending even to a belief in the existence of supernatural and miraculous gifts. But when the fact is once comprehended that in this capacity for uncommon feats of vision, hearing, touch, etc. we observe merely the exaggeration of a process which occurs in every act of attention, the miraculous semblance of the phenomena disappears. Attention implies an increase of activity in certain portions of the brain, with dim-

¹ *Brain*, vol. iii. p. 394.

intution of the function in the remainder of the organ. In the wild excitement of a cavalry charge the soldier feels not the sabre cut which will fill his consciousness with pain so soon as his attention is released from the fetters imposed by the more engrossing events of the combat. So in the somnambulist sleep those parts of the brain which remain awake perform their functions with a vigor that is enhanced by a concentration of cerebral energy in certain restricted portions of an organ that, by reason of its naturally excessive instability, had been previously fitted for the liberation of an inordinate amount of molecular motion. Hence the slightest suggestion of sense may suffice for the most extraordinary perception. Such persons see through their eyelids and hear at a surprising distance. The memory of past events, the recollection of long-forgotten words and thoughts, supplies in this state an abundance of materials out of which an exalted imagination may construct the most astonishing scenes. By this method of combination are produced those remarkable oratorical utterances which by the ignorant have been so widely attributed to the supervision of guiding spirits from another world. In this condition the essential characteristics of the mind of the so-called medium become the real guides of his mental processes. Hence the infinite variety and contrariety of the utterances of such declaimers.

Among other consequences of this exalted susceptibility of the waking portions of the brain may be noticed the effect of suggestions by others upon the mind of the somnambulist. Numerous examples scattered through the literature of the subject¹ illustrate the manner in which the course of our ordinary dreams may be thus directed. The hypnotic dream is far more easily modified.² The simplest manifestations of such influence are exhibited in movements in obedience to the command of the hypnotizer. Next in rank are those more complicated actions that are effected by excitement of the imitative faculties of the subject. Every suggested movement that can be in any way perceived by the patient will be at once reproduced. Various emotions and passions may thus be aroused by simply placing the sleeper in the appropriately suggestive attitudes. Under the influence of a pregnant idea intruded upon the mind of the patient the subsequent association of ideas will suffice for the evolution of a complicated series of hallucinations, as in the case of a young woman, who on being directed to put out her tongue immediately began to feel sensations of uneasiness in her stomach, followed by nausea and attempts at vomiting, accompanied by the impression of being on shipboard. In the lowest grades of the hypnotic state consciousness may remain, and the subsequent recollection of the events of the paroxysm may be quite persistent. In such cases illusions that were produced by suggestions from other minds generally survive in memory and become the causes of serious delusion. Witness the manner in which susceptible individuals, partially hypnotized in a so-called spiritual circle, believe in the reality of the illusions which have occupied their senses during a séance.

A higher degree of insensibility to ordinary impressions is necessary to the production of the phenomena of passive obedience and of automatic

¹ Carpenter's *Physiology*, 8th ed., p. 765; *Le Sommeil et les Rêves*, par L.-F. Alfred Maury, 4th ed., p. 153 et seq.

² *Loc. cit.*, p. 357.

imitation. It is probable that the degree of sensory hyperæsthesia which enables certain hypnotic patients to read the thoughts of others belongs rather to the first than to the last of these classes. This capacity is usually associated with preservation of consciousness and memory, and is, essentially, a mere exaggeration of that power which all possess in greater or less degree. Numerous well-authenticated examples of a surprising manifestation of this faculty have been recorded, so that the possibility of its existence no longer admits of doubt.¹ In all cases it has been remarked that the hypnotic mediums can only respond correctly to questions for which the true answer is present in the mind of the questioner. For all other interrogations the replies are delivered purely under the influence of random suggestion. In certain of these cases the pathway of communication lies through actual physical contact, as in ordinary mind-reading, where the insensible molecular oscillations of the muscular elements of one individual serve to guide the movements of another. But more frequently the transmission of ideas is effected through the eyes. With these organs the table-rapper or the planchette-writer reads the unspoken words of the questioner in a manner very like, yet vastly more deliberate than, that by which deaf-mutes now learn to interpret the movements of the lips of persons with whom they converse. This fact is well illustrated by the experience of Maury² in an interview with a celebrated table-rapper, who without the slightest hesitation made known to him the age, name, and date of death of a brother whom he had lost. She also gave the same information regarding his father, and related the names of other persons upon whom he had fixed his attention. But if he turned away his face or concealed his eyes, so that the woman could no longer watch their expression, her responses ceased to be of any value.

In these partial developments of the hypnotic state it is worthy of note that the phenomena of sleep are so few and so comparatively insignificant that they are usually overlooked. Hence the veil of mystery which has so often obscured the interpretation of such cases. Careful observation, however, will always detect some characteristic departure from the normal standard—some loss of balance between the different parts of the nervous system—by means of which the true relations of each example may be determined.

TREATMENT.—A large proportion of the phenomena of somnambulism and hypnotism depend rather upon an originally irritable organization than upon a specially diseased condition of the nervous system. Their treatment, therefore, frequently resolves itself into the management of hysteria or of cerebrasthenia. But if the manifestations of somnambulism develop for the first time in a person advanced in years, who has previously enjoyed good health and a sound mind, it should be regarded as an omen of grave import, signifying the imminence of organic cerebral disease. Though the meaning of such incidents is less sinister in early life, they reveal an ill-balanced state of the nervous system and an imperfect process of nutrition in the growing body. Such children are the

¹ Luther V. Bell, *Two Dissertations on what are termed the Spiritual Phenomena*, read at the meetings of the Association of Medical Superintendents of American Insane Hospitals at Washington and Boston in 1854 and 1855.

² *Le Sommeil et les Rêves*, 4th ed., p. 361.

frequent victims of night-terrors, the form of disorder most commonly evolved by their somnambulistic proclivities. The treatment of night-terrors should therefore be chiefly directed to the invigoration of the general health of the patient. Indigestion and malnutrition are among the most prominent antecedents, and they should constitute the principal objects of therapeutical attention. Constipation is usually present. This may be relieved by the use of compound rhubarb powder or any other gently stimulating laxative. Digestion should be aided with pepsin as soon as the catarrhal condition of the alimentary canal, so uniformly present, has been measurably improved. Cod-liver oil or its substitutes should be administered for a long period of time. If the nocturnal paroxysms be frequently renewed, it may be well to employ the bromides, either with or without chloral hydrate; but as a general rule it is better to rely upon hygienic and restorative treatment, rather than upon any form of merely hypnotic medication.

INSOMNIA.

THE departures from the course of natural sleep which have been thus considered are not so much the direct consequence of acute disease as the result of structural deviation from the normal type of the nervous system. We must now briefly review the strictly pathological modifications to which sleep is liable.

Lithæmic Insomnia.

Among those who indulge freely in the pleasures of the table a form of insomnia is not uncommon. Originating at first in mere overloading of the stomach, and consisting in a direct irritation of the brain through the medium of the intervening nervous apparatus, sleeplessness finally becomes a symptom of more serious mischief. The tissues become charged with nitrogenous waste, and a lithæmic¹ or gouty condition is established. Such patients are wakeful, or if they sleep their slumbers are imperfect and unrefreshing.² Grinding of the teeth,³ noticed by Graves during the sleep of the gouty, is a symptom indicative of a highly irritable condition of important ganglia at the base of the brain. These symptoms are sometimes associated with turgidity of the superficial vessels of the head, indicating imperfect function of the circulatory organs, with a tendency to accumulation of the blood in the venous channels of the body. The sleep of such partially-asphyxiated patients is fitful, irregular, and akin to stupor. Occurring in the subjects of periodical gout, these disturbances of sleep become increasingly serious as the paroxysm is approached, until loss of sleep and the unrefreshing character of such

¹ DaCosta, "Nervous Symptoms of Lithæmia," *Am. Journ. Med. Sci.*, Oct., 1881.

³ Trousseau, *Clinical Medicine*, Am. ed., vol. iv. p. 362.

slumber as may be obtained become important factors among the causes of failing health.

For all such patients a proper recognition of the cause of their disorder is essential. This must be corrected by measures appropriate to the treatment of the gouty diathesis. Since the condition of the cerebral tissues is a state of irritation caused by the presence of excrementitious substances, such hypnotic remedies must be selected as will not interfere with the defecation of those tissues. Bromide of potassium, valerian, scutellaria, hyoseyamus, hops, and cannabis indica are useful, together with all that class of drugs which quiet the brain without hindering the process of excretion. Chloral hydrate often produces an excellent result, but care should be taken to prevent its habitual use.

Febrile Insomnia.

Closely related with the sleeplessness of lithæmia are the disturbances of repose which attend the evolution of the various specific fevers. In many cases the condition varies all the way from stupor to delirium. Excessive somnolence, such as often ushers in the fever, is an indication for evacuant treatment. Cerebral excitement calls for remedies like the bromides and chloral hydrate, which do not interfere with elimination. If pain, like headache or backache, be a symptom demanding attention, the addition of morphia in small doses forms a valuable reinforcement for the hypnotic mixture; but, as a general rule, opiates should be used with a sparing hand. The various resources of hydrotherapy are often invaluable when wakefulness results from the cutaneous irritability of the eruptive fevers. During the later stages of a protracted illness the occurrence of insomnia should direct attention to the nutrition of the patient. Wakefulness is then the symptom of an irritable weakness of the brain, demanding remedies which delay the process of disassimilation. The failing power of the heart requires attention, and diffusible nutriment must be given to convey the elements needful for restoration of the exhausted brain. These indications are most perfectly answered by the associated administration of opiates with alcohol, milk, and beef-juice in small and frequent doses.

Insomnia from Exhaustion.

Cerebral exhaustion is a not uncommon cause of wakefulness in cases uncomplicated with fever. It is usually the result of chronic conditions of ill-health and depression, such as are often encountered as the result of various cachexias or of dyspepsia, with or without the abuse of alcohol, tea, coffee, or tobacco. Overwork, debilitating discharges, pregnancy, parturition, mental anxiety, depressing emotions, chronic heart disease, and incipient insanity are fruitful causes of the exhaustion which produces this most distressing form of insomnia. In such cases the cessation of healthy nutrition leads to a condition of excessive instability in the cerebral tissues. The oxygen which they receive from the blood is not stored with any degree of permanence, but tends to pass directly into

stable combinations with the oxidizable elements of the brain. Consciousness is thus continually aroused. The state of such a patient presents a very close analogy to the condition of the victim of diabetes whose liver refuses to retain its glycogen. The inordinate discharge of sugar into the blood not only exhausts the tissues of the liver, but also excites other organs—notably the kidneys—to excessive and unwholesome activity. In somewhat similar fashion, the failure of the brain to assimilate and to retain oxygen leads to an abnormal intramolecular oxidation, which excites an excessive and unwholesome activity on the part of the Ego in another region—namely, in the field of consciousness. Such wakefulness might justly be termed a psychical diabetes.

This variety of insomnia has frequently been ascribed to cerebral anæmia occurring as a part of a general spanæmia. But this universal impoverishment of the blood, though a sufficient cause of the morbid instability, the irritable weakness, of the cortical tissues, does not necessarily imply a comparatively bloodless condition of the brain. Unequal circulation and local hyperæmia in different organs of the body are no unusual consequences of the anæmic state. Slight disturbances suffice to arouse the brain of such a patient. The vaso-motor apparatus shares in the general irritability, permitting blood to inundate the cortical substance almost without provocation. The unstable protoplasm is only imperfectly renovated, usually at the expense of the other tissues of the body. The weary patient, busying himself with an unwilling review of the events of the day, tosses long upon his couch before he can secure the approach of “tired Nature’s sweet restorer, balmy sleep.” When at length he yields, his slumbers are brief, and the latter part of the night is but a repetition of the earlier vigil.

Such patients need a very radical course of general treatment. A complete change of habits should be effected. A long vacation in the country, or, best of all, a protracted voyage in a sailing vessel, is desirable. Hot foot-baths, with cold affusion upon the head, and warm sponge-baths, or even the full bath in tepid water, at bedtime, are of great service as means of tranquillizing the nervous system. The indications for medicinal treatment, besides attention to the predisposing cachexia, are two-fold—to calm and to nourish the enfeebled nervous substance. Opiates calm, but do not nourish—they hinder the process of nutrition; hence the sufferer wakes unrefreshed by the sleep which they procure, and is soon in a condition worse than ever. The same objection lies against the continuous use of the bromides. But alcohol and its hypnotic derivatives (chloral, paraldehyde, etc.) not only calm the excitable brain, but they also furnish to the tissues a certain amount of diffusible nutriment which suffices to steady the brain until a change of occupation, with rest and wholesome food, can produce a complete restoration of its normal stability. To this effect of alcohol must be ascribed its value as an hypnotic in the wakefulness of old people who cannot sleep without a preliminary night-cap. A moderate draught of hot toddy in such cases serves to arouse the feeble heart and to equalize the circulation by the production of a moderate degree of general vascular dilatation. The sugar and water afford an easily assimilated food, while the alcohol benumbs the cortical protoplasm to a degree which favors the cessation of conscious perception. If administered in excessive doses, it is not sleep but anæsthetic intoxication

which follows. If this condition be unduly repeated, the phenomena of chronic alcoholism supervene, with all the horrible forms of insomnia that accompany cerebral starvation and delirium tremens. Non-alcoholic nerve-stimulants and tonics, with careful administration of easily-digested food, are then more than ever needed to overcome the neurasthenic wakefulness.

Insomnia from Active Cerebral Congestion.

Still another form of sleeplessness is often experienced as a result of actual inflammation in some portion of the body, either involving the intracranial contents directly or reacting upon the brain through the medium of its circulation. In such cases many of the symptoms of acute inflammation are present. The head aches, the temples throb, the face and eyes are suffused with blood, the temperature is considerably increased. The senses become exalted, ideas pursue a tumultuous course, there may be actual delirium. These disturbances are due to an active hyperæmia of the brain. The substance of the cortex becomes hyperexcitable, and the ordinary incitements of sense produce an exaggerated effect in consciousness. The patient does not sleep, and he feels no need of sleep, because the nutrition of the brain is sustained at the expense of the remainder of the wasting body. The most speedy and effectual relief in such cases is obtained through a diminution of the current of blood in the brain. Moderate compression of the carotid arteries has been proposed as theoretically useful. Sedatives, like aconite, conium, digitalis, veratrum viride, ipecacuanha, and tartar emetic are useful, either alone if pain be absent or combined with opiates if the patient is suffering. Dover's powder or tartar emetic and morphia in small doses was formerly in general use. If there be a disposition to nausea the substitution of aconite for antimony is of great value. A combination of morphia, bromide of potassium, and chloral hydrate often gives excellent results. Paraldehyde may be preferable to chloral by reason of its more thoroughly sedative effect. Derivative measures—mercurial cathartics, cupping, leeching, or even general bleeding—may become necessary in certain cases. After the acute stage is passed blisters behind the ears should be employed. In the sleeplessness of acute mania Newington¹ has used mustard baths with great satisfaction.

Coma.

Turning now to the other extreme, we find a class of cases in which the disorder consists not in wakefulness, but in an excess of sleep. Excluding those exceptional cases in which healthy individuals, as a consequence of inordinate physical exertion, have slept for many hours beyond their ordinary limit, every extraordinary manifestation of sleep-like unconsciousness must partake of the nature of coma. Between natural sleep and this condition may be placed the distinction that the one is always the effect of natural physiological processes, while the other is always the result of injury, of disease, or of some form of intoxication. Comatose

¹ *Brain*, vol. i. p. 126.

unconsciousness may be the result of cerebral compression caused by traumatic impact or by the presence of inflammatory exudations. Intracranial tumors, embolisms, thrombi, degeneration of tissue, diseases of the arteries of the brain—in short, every morbid change of which the liquids and the solids within the cranium are capable—may become the causes of coma. So also the blood and lymph, contaminated with the products of internal disintegration, may benumb the brain with comatose sleep. Again, the tissues of the brain may be overwhelmed with poisons introduced from without the body, and thus a condition of coma may result. Few diseases, therefore, exist without the possibility of coma as one of their consequences—a coma which, however, must not be confounded with the genuine sleep which sometimes occupies the larger part of certain stages of convalescence from acute illness. During such convalescence there is a reversion to the infantile type of nutrition, with all its need of prolonged and frequent periods of repose. Like normal sleep, the comatose condition admits of considerable variation of intensity. The patient may sometimes be partially roused, as from the coma of alcoholic intoxication, and he may finally recover complete consciousness, but very often the reverse is the fact. The coma deepens into paralysis, and death terminates the scene without the slightest manifestation of sensibility or intelligence.

Sleeping Dropsy (*Maladie du Sommeil*).

A singular disorder, characterized by daily paroxysms of somnolence, tending to become more and more continuous and profound until merged in fatal coma, is encountered among the negro inhabitants of the Atlantic coast of tropical Africa. Similar cases have been occasionally reported in other regions of the world, but it is among the Africans that they have been principally observed. For our knowledge of this disease we are chiefly indebted to the writings of Clark,¹ an English surgeon residing at Sierra Leone, and of Guérin,² a surgeon in the French navy, who enjoyed unusual opportunities for its study among the laborers recently brought from Africa to the island of Martinique. According to these observers, the onset of the malady is gradual, commencing with a slight frontal headache. Very soon a disposition to sleep after meals is remarked. This becomes increasingly urgent, and the paroxysms of sleep are prolonged, until at length the patient becomes continually soporose. The wakeful intervals are marked by a sluggish state of the intellectual faculties. The pulse is not accelerated, but remains full and soft. The veins of the sclerotic become turgid and the eyeball seems unusually prominent. The temperature does not increase, but rather tends to diminish its figure. The skin becomes dry and moderately cool. The tongue continues moist, and is covered with a white fur. The contents of the bowels and of the bladder are regularly voided, and the appetite persists with considerable vigor. Finally, the patient becomes completely comatose and dies quietly. Sometimes, however, the evolution of the disease is less tranquil. Epileptiform convulsions, followed by progress-

¹ *Transactions of the London Epidemiological Society*, vol. i. p. 116.

² *De la Maladies du Sommeil*, 1869.

ively deepening paroxysms of coma, interrupt its course, until a continuous muscular tremor marks the closing period. At the same time the pulse grows weaker and more frequent, until its movements cease in death. Recovery is almost unknown, though the duration of the disease often varies from three months to a year or longer. Examination of the body after death has thus far yielded very negative results: the sinuses and larger vessels of the brain are engorged with blood, but no evidence of inflammation is anywhere apparent. The other organs present no pathological alterations whatever. These observations seem to indicate that the disease originates in some form of general blood-poisoning rather than in any local inflammation or degeneration, and Clark has called attention to an enlargement of the cervical glands as a feature of the malady. According to G. H. Bachelder,¹ the native physicians cure the disease by extirpation of the affected glands. He has also observed an initial lesion in the nasal mucous membrane. If this be confirmed, the malady will take its place among the forms of coma produced by septic poisoning.

Lethargy.

A pathological variety of sleep, in which the repose of the body is even more complete than in coma. The victim of coma often presents a countenance suffused with blood; the pulse beats vigorously, and respiration may become stertorous. But in lethargy the abolition of bodily movements is almost total. In the milder forms of this disorder the patient may be partially roused, so as to attempt an answer when addressed, appearing like a person in very profound sleep; but in the majority of cases he remains insensible, unconscious, and utterly irresponsive to ordinary forms of irritation. Respiration and circulation are reduced to a minimum, even becoming for a time imperceptible. Uncomplicated with hysteria, the disorder is rapidly fatal, but according to Rosenthal² hysterical lethargy is never mortal.

Many examples of this disorder have been furnished by the records of apparent death.³ I am well acquainted with a lady who in early childhood was laid out for burial at the supposed termination of some infantile disease. Her mother alone insisted that the child was still alive. After some time spent in weeping and expostulation, she applied a blister to the thorax of the babe, who at length began to exhibit signs of consequent irritation, followed by a complete recovery. Still more instructive is the case related by Rosenthal⁴ of a young woman twenty-four years of age who in consequence of violent emotional excitement became unconscious and presented no sign of life, though tested with a mirror before the mouth and by dropping melted sealing-wax upon the skin. On raising her eyelids the pupils gave no response to light; the limbs remained perfectly placid and the radial arteries were motionless. Careful auscultation, however, detected a very feeble and intermittent sound in the cardiac region. The thorax exhibited no movement, but the lateral surfaces of

¹ *The Medical Record*, July 1, 1882, p. 23.

² *Real Encyc. der ges. Heilkunde*, vol. viii. p. 276.

³ See article "Mort apparente," *Dic. Encyc. Sci. méd.*, 2d Series, vol. ix. p. 593.

⁴ *Loc. cit.*, p. 272.

the abdomen presented a slow and almost imperceptible oscillation. Gentle faradization of the muscles and nerves of the face and hand aroused definite muscular contractions. By these observations Rosenthal became satisfied that, although the patient had remained for thirty-two hours in this condition, she was only apparently dead. In fact, after continuing forty-four hours in a state of suspended animation she awoke spontaneously, made a rapid recovery, and enjoyed as tolerable health as an excitable nervous temperament would permit.

Apparent Death.

Certain authors make a distinction between lethargy and apparent death. But, leaving out of view the cases of so-called lucid lethargy, a variety of the trance state, the difference is rather one of degree than of kind. The movements of respiration and of circulation, though greatly diminished, are readily observed in ordinary forms of lethargy, while in apparent death the pulse can no longer be discovered, and only the faintest sound can be distinguished in the region of the heart. It therefore becomes imperative to have within reach a crucial test of the persistence of general vitality. Such a test, according to Rosenthal, exists in the faradic current. Within two or three hours after genuine death the muscles cease to be excitable by the induced current, but in a case of apparent death this form of electro-muscular contractility never disappears. Every other test that has been proposed has failed under certain circumstances. This alone gives uniformly positive indications.

Lucid Lethargy.

In certain cases of apparent death the patient presents the external phenomena of suspended animation, but the power of conscious perception does not cease. The senses of sight and hearing remain, and are perhaps intensified by inhibition of the power of projecting cerebral volitions into space. The sufferer hears and sees; perception, memory, reasoning, judgment, emotion, volition, all persist. The possibility of centrifugal projection from the sphere of consciousness into the realm of space seems to be the only thing that is wanting.

The victims of this form of apparent death are usually women, or men who are characterized by a feminine nervous organization. Great mental excitement, fatigue, semi-starvation, and exhausting diseases are the principal proximate causes of the event. The following case, which was observed by my friend P. S. Hayes of Chicago, illustrates all these facts: A female physician, about thirty years of age and consumptively inclined, after a long and wearisome hospital service was attacked with typhoid fever. After a period of great prostration the hour of death seemed to have arrived. In the presence of her physician and surrounded by her relatives she ceased to breathe and the pulse stopped. Bottles of hot water were applied to the limbs, and other methods of restoration were employed, but a number of hours elapsed before these efforts yielded any result. At last she began to breathe once more; life was resumed and

a gradual recovery followed. During all this time of apparent death consciousness had been preserved. She seemed to be looking down from above her bed, by the side of which she could see the physician holding her wrist, and she felt grief at witnessing the sorrow of her friends. Ordinary sensation was suspended, for she did not feel the scalding heat of the bottles that were applied to her limbs. Borne upon the wings of a liberated imagination, she thought she beheld the celestial city, but might not enter within its gates. In this exaltation the reasoning faculties also shared, so that certain philosophical problems which had long baffled her intellect were now perfectly comprehensible, and the memory of their interpretation persisted after recovery.

Many similar narratives have been duly authenticated, but the limits of the present article will not permit a discussion which properly belongs to an investigation of the phenomena of trance. The important fact for present consideration is the persistence of conscious life despite the appearance of death. In this preservation of consciousness, notwithstanding temporary suspension of certain forms of sensibility, together with loss of the power of voluntary motion, may be discovered a relationship between the events of lucid lethargy and various somnambule modifications of sleep which have been previously passed in review.

ACUTE AFFECTIONS PRODUCED BY EXPOSURE TO HEAT.

By H. C. WOOD, M. D., LL.D.

THERE are two distinct diseases—or, more correctly, conditions—of the human body which are produced by exposure to heat, and which have a certain similarity in their symptoms, but are very different in their immediate pathology and require directly opposite methods of treatment. Although their individuality was pointed out as long ago as 1851 by the late D. F. Condie of this city,¹ yet they have been frequently confounded by writers upon the subject, and the terms heat-exhaustion and sun-stroke have not rarely been used as strictly synonymous. In the present article it is proposed to consider them as separate affections under the respective names of heat-exhaustion and thermic fever.

Heat-Exhaustion.

Any one who has been long exposed to a high temperature under circumstances requiring physical exertion must have noticed the feeling of general weakness and relaxation which results. Thus far reaches our every-day experience, but cases in which acute symptoms are severe enough to cause alarm occur, although somewhat infrequently. The attack may come on slowly, but may be as abrupt as that of true sun-stroke, and the severest cases may happen in those who have been in robust health as well as in the weak and feeble. The mind is usually clear, the pulse rapid and feeble, the surface cool, the voice very weak, muscular strength greatly lessened, and the feeling of exhaustion extreme. If this condition be intensified, syncope may be developed with its usual symptoms. In all this there is nothing peculiar and little that is necessary to notice here; but there is a form of heat-exhaustion in which the heart does not seem to suffer principally, but in which there is collapse with palsy of the vaso-motor system, great fall of the bodily temperature, and marked general nervous symptoms. At the International Exhibition of 1876 a very powerful man, whilst working in an intensely hot, confined space, fell down without giving warning, and was brought into the hospital. He was in a state of restless, delirious unconsciousness, incessantly muttering to himself, and when shaken and shouted at responding only by a momentary grunt. The pulse was rapid, fluttering and feeble. The

¹ *Amer. Journ. Med. Sci.*, Jan., 1852.

surface was covered with a very heavy sweat and exceedingly cold. The muscular relaxation was extreme. The facies was that of collapse, and the temperature, as taken in the mouth, 95.25° F.

The PATHOLOGY of heat-exhaustion is best discussed in conjunction with that of thermic fever, and will therefore be for the present postponed.

The TREATMENT of heat-exhaustion is a very obvious one. The indications are to stimulate the circulation and warm the body by external heat with an energy proportionate to the severity of the attack. In mild cases the exhibition of a whiskey punch or similar beverage may suffice, but in severer attacks alcohol acts too slowly and is not capable of filling all the indications. It may re-excite the flagging heart, but it is probably not a vaso-motor stimulant, and if given too freely may even increase the vaso-motor depression. Digitalis is an excellent stimulant of the heart, and probably also of the vessels. It acts, however, comparatively slowly even when hypodermically injected, but in severe cases it should always be employed. The tincture is the most eligible preparation, and when injected under the skin in doses of fifteen drops causes no local irritation. Ammonia would be a very valuable remedy did not its use offer so many difficulties of administration: injected into the cellular tissue, it causes great pain and usually sloughing, and its intravenous use is by no means always easy. As a vaso-motor stimulant atropia is an excellent remedy, and, as it has also a very powerful influence in arresting the secretion from the skin and in raising the animal temperature, it should produce very good results in the peculiar form of collapse under consideration.

When the bodily temperature is below normal the most important measure of treatment is the use of the hot bath: the water should be from 100° to 120° F.—*i. e.* as hot as can be borne—and the whole body should be immersed in it until the mouth temperature becomes normal.

Thermic Fever.

SYNONYMS.—Coup de soleil, Sunstroke, Heat apoplexy, Heat asphyxia, Heat fever, Sun fever, Thermohaemia, Erethismus tropicus, Insolation.

The immediate cause of thermic fever is always exposure to excessive heat in some form. As the body can cool itself much more readily in a dry than in a moist atmosphere, it is able to resist the influence of a dry, overheated air much better than when there is also moisture. It is for this reason that sunstroke is so much more infrequent upon the high table-lands of Abyssinia or in the dry belt of our Texan prairies than in the lowlands of India or upon our own seacoast. For the same reason it is especially prone to attack indoor workers in confined, moist factories, and especially in laundries and sugar-refineries. At one time it was thought that exposure to the direct rays of the sun was the chief cause of the disease, but there is now abundant clinical testimony to the fact that such exposure is in no sense necessary. Without occupying space in giving detailed references, it suffices, as an illustration of the fact that the most complete darkness is no protection, to allude to the epidemic upon the French man-of-war *Duquesne*, as recorded by M. Boudin, in which a

hundred cases of sunstroke occurred in a short time, most of them at night when the men were lying in their bunks. Bonniman¹ says: "By far the greater number of cases that yearly occur in India are of men who have not been exposed to the sun. It is not unusual for men to go to bed in apparent health, and to be seized during the night; and patients in hospitals who have been confined to bed for days previously are frequently the subjects of attack."

Although the immediate cause of the attack is excessive heat, there are certain conditions which act as predisposing causes by lessening the power of the system to resist the heat, or, in accordance with the theory of sunstroke which I believe established, by so weakening the inhibitory heat-centre that it is readily exhausted. The chief of these predisposing causes are race, excessive bodily fatigue, and intemperance. It is true that males are much more frequently affected than females; thus, in an epidemic occurring in St. Louis, Missouri, in 1878, there were 115 deaths in males and 39 in females. This is due, however, not to one sex being predisposed to the attacks, but to the habitually greater exposure of males than of females to heat. The much greater frequency of sunstroke in the laboring than in the upper classes has similar explanation.

Those races which are least accustomed to a tropical climate are most apt to be attacked; thus, both in this country and in India, Europeans suffer far more than do the natives. No race is, however, absolutely exempt. Even the negro and the Hindoo inhabitant of tropical India are occasionally prostrated.

The general experience in the United States shows that habitual excess of alcohol very strongly predisposes to attack, but some of those who have had widest experience in India are inclined to deny this. It has been especially noted in India that persistent bodily fatigue greatly weakens the resisting power of the European. As an instance of this may be cited the case of the Forty-third regiment of the line during the Sepoy rebellion, as recorded by its surgeon, Barclay. It had made a most extraordinary march of over eleven hundred miles, chiefly through the lowlands of India, and at the hottest season of the year. This march was continuous, with the exception of a few brief halts. No cases of sunstroke occurred until nine hundred and sixty-nine miles had been traversed and the men had become thoroughly exhausted and even markedly emaciated. Shortly after this the regiment rested some eight days, and then started again, arriving soon in a narrow ravine in the Bismarunge Ghat, with precipitous walls nearly a mile in height. During the day the thermometer in the tents ranged from 115° to 127°, and on one occasion was noted 105° at midnight. The number of cases of insolation now became very great, and, although most of them recovered, 2 officers and 11 men were lost in the four days during which the regiment remained encamped. The air became cooler as the command emerged from the hills, yet 7 more fatal cases occurred in three days.

SYMPTOMS.—Under the name of ardent continued fever, or *febris continuis communis*, has been described in India an affection which may be considered as representing a mild form of thermic fever. In C. Morehead's clinical work *On the Diseases of India* the following account of the symptoms is given: "The attack is generally sudden, often without

¹ *Edinburgh Med. Journ.*, vol. xiv. p. 1029, 1864.

much chilliness. The face becomes flushed; there are giddiness and much headache, intolerance of light and sound. The heat of skin is great; the pulse frequent, full, and firm. There is pain of limbs and of loins. The respiration is anxious. There is a sense of oppression at the epigastrium, with nausea and frequent vomiting of bilious matters. The bowels are sometimes confined; at others vitiated discharges take place. The tongue is white, often with florid edges. The urine is scanty and high-colored. If the excitement continues unabated, the headache increases, and is often accompanied with delirium. If symptoms such as these persist for from forty-eight to sixty hours, then the febrile phenomena may subside, the skin may become cold, and there will be risk of death from exhaustion and sudden collapse. In most cases the cerebral disturbance is greater in degree, and in these death may take place at an earlier period in the way of coma."

Until very recently the existence within the United States of this class of cases has not been recognized. But in a very able article in the *Therapeutic Gazette* of March 16, 1885, John Guiteras shows that the so-called typhoid fever of Key West is the disease described by Morehead.

In the *Philadelphia Medical Times*, vol. v. p. 664, C. Comegys calls attention to the cases of entero-colitis which are so abundant in the young children of our cities during the hot months. The immediate enormous rise of the mortality-rate among children which always accompanies a marked rise of temperature during July or August indicates very strongly that excessive heat is the chief factor in the production of the disorder. The symptoms may be summed up as high fever, dry tongue and mouth, rapid pulse and respiration, intense thirst, vomiting, purging of greenish, watery, fecal or serous matters with undigested particles of food, and more or less pronounced evidences of cerebral disturbance, such as insomnia, headache, contracted pupils, delirium, and finally coma. In some cases the bodily temperature rises before death to a point comparable with that it reaches in sunstroke of the adult. As pointed out first by Comegys, these cases are almost uniformly relieved by cold water used either, as Comegys himself employs it, in the form of cold affusions practised until the temperature of the child becomes normal, or, as, according to my own experience, is preferable, simple cold baths administered every two to three hours, with just sufficient vigor to produce the desired effect.

Thermic fever in the adult and in this latitude is usually first seen by the physician after the stage of insensibility has been reached. In many cases this condition comes on with great suddenness, but in other instances there are distinct prodromata, such as inaptitude and disinclination to exertion, vertigo, headache, confusion of ideas, great oppression or distress at the præcordia or epigastrium, and disturbances of the special senses. Swift has noticed a peculiar chromatopsia, the sufferer seeing everything of a uniform color, in most cases blue or purple, but in others red, green, or even white, and W. H. Kesteven¹ has reported a case in which a man, after exposure to an excessively hot sun, was seized with severe headache, saw everything red or green, and had for some days a distinctly impaired color-sense.

At one period I saw a large number of advanced cases of sunstroke in

¹ *Trans. Clin. Soc. of London*, 1882, xv. 101.

the hospital, and the symptoms were quite constant. Total insensibility was always present, with, in rare instances, delirium of the talkative form, and still more rarely the capability of being roused by shaking or shouting. The breathing was always affected, sometimes rapid, sometimes deep and labored, often stertorous, and not rarely accompanied by the rattle of mucus in the trachea. The face was usually suffused, sometimes, with the whole surface, deeply cyanosed. The conjunctiva was often injected, the pupils various, sometimes dilated, sometimes nearly normal, sometimes contracted. The skin was always intensely hot, and generally, but not always, dry; when not dry it was bathed in a profuse perspiration. The intense burning heat of the skin, both as felt by the hand and measured by the thermometer, was one of the most marked features of the cases. The degree of heat reached during life was, in my cases, mostly 108° – 109° F., but it sometimes reaches 112° F. The pulse was always exceedingly rapid, and early in the disease often not wanting in force and volume; later it became irregular, intermittent, and thready. The motor nervous system was profoundly affected: subsultus tendinum was a very common symptom; great restlessness was also very often present, and sometimes partial spasms or even violent general convulsions. The latter were at times epileptiform, occurring spontaneously, or they were tetanoid and excited by the slightest irritation. Sometimes the motor system suffered paralysis, the patient moving neither hand nor foot.

This extreme motor relaxation, which in my observation is rare, seems to have been very common in the epidemic described by Barelay,¹ as he states that in a large proportion of the cases, from the commencement of the attack until its termination in death, the patient never moved a limb or even an eyelid. Petechiæ and ecchymoses, the evidences of broken-down blood, were present in some of my cases, and there was in one or two instances a fetid hemorrhagic exudation from the nostrils during life. A symptom which has almost escaped the attention of authors was a peculiar odor, which was most marked in patients who had involuntary passages, but was very distinct from any fecal odor. The stools emitted it very strongly, but so did the skin and breath. It was so distinctive as to render possible the recognition of a case by the sense of smell alone. The discharges from the bowels were liquid and very often involuntary. None of my cases passed urine whilst under observation.

It is plain that the symptoms of coup de soleil, as usually seen, may be summed up as those of intense fever, accompanied by profound nervous disturbance (as manifested by insensibility with or without delirium, and by motor symptoms, such as convulsions or paralysis), by arrest of glandular action, and by changes in the blood. In this ordinary form of sun-stroke death takes place by asphyxia or by a slow consentaneous failure of both respiration and cardiac action. It very rarely occurs in less than half an hour after the first decided symptoms, and usually is postponed for a much longer period.

There is a form of coup de soleil in which death results almost at once, and probably always by cardiac arrest, and to which the name of the cardiac variety may well be given. It is very rarely, if ever, met with in civil life, and among soldiers is especially seen during battle or at other

¹ *Madras Quarterly Journal*, 1860, 364.

times when great exertion is being made. These cases will be more fully discussed in a later portion of this article.

POST-MORTEM CHANGES.—Owing to the excessive heat of the body, putrefactive changes occur very rapidly after death from sunstroke, and various described lesions, especially of the heart, have been undoubtedly the result of post-mortem changes. Later observers have confirmed my original observation, that if the body be opened directly after death the left ventricle will be found firmly contracted, though the right heart and the pulmonary arteries, with their branches, are gorged with dark fluid blood. In my cases the lungs did not present at all the appearance of congestion of their minute capillaries, but when they were cut the blood poured from them abundantly, seemingly from their larger vessels. Not only do the lungs suffer from venous congestion, but the whole body also. The blood appears to leave, as it were, the arterial system and collect in the venous trunks. The arterial coats are often stained red, apparently by the broken-down red corpuscles of the blood.

There can be no doubt that the blood suffers in sunstroke very similarly to what it does in low fevers. Its coagulability is impaired, but not always destroyed; and it is possible that in the very rapid cases it may not be decidedly affected. After death it appears as a dark, often thin, sometimes grumous fluid, whose reaction is very feebly alkaline, or, as I have seen it, even decidedly acid. Levick¹ appears to assert that the blood-discs, as seen by him under the microscope, were shrivelled and crenated, and showed very slight tendency to adhere in rouleaux. In several of my cases the blood was carefully examined by the microscope, but nothing abnormal was found. The extravasations of blood which have been found by K. Köster in various parts of the nervous system are probably of the nature of petechiæ, the results of the altered blood-crisis, and not due to any especial affection of the nerve-centres.

THEORY OF THE DISEASE.—The theories which have been brought forward as explanatory of the phenomena of sunstroke are so various that it would be impossible in the limits of this paper to discuss them. It does seem, however, proper to give a very brief historical sketch of the development of our present knowledge of the subject. In 1854, H. S. Swift² said that the disease is "now generally admitted to be merely exhaustion produced by fatigue," although he recognized the existence of an "apoplexy produced by insolation." The cases which Swift so well describes as those of heat-exhaustion were true instances of thermic fever. The physicians of the Pennsylvania Hospital, especially Gerhard, early called attention to the resemblance of sunstroke to a fever, but it was not until January, 1859, that their views found expression in print in the paper published by James J. Levick in the *American Journal of Medicine*. This observer tabulated the post-mortem appearances of typhus fever and of sunstroke in contrast, calling attention also to the similarity of symptoms during life. In 1863, H. C. Wood³ claimed distinctly that sunstroke is a fever due to the development of a poison in the blood, and gave to the disease the name of thermic fever. To R. Cresson Stiles is due the credit of having first proven⁴ the possibility of producing in animals a sunstroke with symptoms and path-

⁴ *Boston Med. and Surg. Journ.*, June, 1864, p. 349.

ological changes similar to those which occur in man. He also came to the conclusion that the symptoms are the results of the direct action of heat, especially upon the muscular system. He says: "The dilatation of the capillaries is explicable by the direct effect of the heated blood upon the muscular fibres of the arteries and the arterioles. The cerebral symptoms and the full and forcible pulse may also be due to this dilatation." George B. Wood, in the sixth edition of his *Practice of Medicine* (Philadelphia, 1866), wrote an elaborate article upon the disease, giving it the name of heat fever, and affirming that it "is, I believe, strictly an idiopathic fever." He further asserts: "In heat fever all the organs, the brain, heart, lungs, stomach, kidneys, etc., are excessively stimulated by the great heat, and all exhibit disorder and at length depression of their functions." The article of George B. Wood was not based upon experimental researches, but upon a very philosophic rendering of the clinical phenomena, and was a carrying out of the ideas which had permeated the medical teaching of the Pennsylvania Hospital.

About 1869, Eulenberg and Vohl¹ advanced the theory that death from sunstroke is the result of the sudden liberation of gases in the blood; and Weikard affirmed that the death is due to the increase of the coagulability of the blood and consequent formation of clots in the vessels, being in this supported by Richardson of London.² Contrasting with these in its being really an important contribution is the article of Vallin:³ its chief merit is the conception of the idea of the local heating of isolated parts of the body, and the devising of a plan for carrying the idea into effect. The experiments of Vallin did not themselves prove very much, and led him to the erroneous conclusion, first, that the death in sunstroke is the result either of a coagulation of the left ventricle or else of a disturbance of the innervation of the heart by an action of the heat upon the nerve-centres in the base of the brain; second, that these two forms of death correspond to sthenic and asthenic varieties of insolation—varieties which, I believe, have no proper existence.

The first experiments of Claude Bernard upon the action of external heat were given in a lecture upon muscular respiration on May 3, 1864, published in his *Leçons sur les Propriétés des Tissus vivants* (Paris, 1866). They were merely incidental to another research, and simply showed that when a warm-blooded animal was exposed to heat it died, the death being, according to the observations of Bernard, the result of cadaveric rigidity suddenly attacking the heart. The more elaborate researches of Claude Bernard upon the effect of exposure of animals to external heat, so far as I have knowledge, were not published in detail until after the nature of sunstroke was determined, although the lectures were delivered in the years 1871 and 1872; they may be found reported in full in his *Leçons sur la Chaleur animale, sur les Effets de la Chaleur, et sur la Fièvre* (Paris, 1876).

It is proper also to state here that some of the physicians of India had previous to this time more or less imperfectly recognized the relation of sunstroke to fever, but, I believe, none of them distinctly postulated the theory.

The above historical sketch shows that by many authors the relation

¹ Virchow's *Archiv*, t. lxii.

² St. Bartholomew's *Reports*, vol. vii.

³ *Archives générales de Médecine*, Février, 1870.

of sunstroke to fever had been more or less dimly perceived, and that George B. Wood had very clearly stated the true nature of the affection, in that it was simply the result of the direct action of heat. Such statement, however, not resting upon proof, had not been accepted: it was also wanting in detail, and where such details were attempted the surmises were not always correct. Under these circumstances my researches, made in 1870 and 1871, and first published in 1872, led to the complete understanding of the affection.

The space allotted to me in the present volume will not allow of any detailed account of my experiments, but I shall quote from my summing up of the results obtained by them. It was shown that sunstroke may be produced in animals as readily as in man either by natural or artificial heat; that the symptoms are similar to those seen in man; that death takes place ordinarily by asphyxia; that after death the characteristic lesions are alteration of the blood and rigidity of the heart, with immediate or quickly-appearing post-mortem rigidity of the general muscular system; that this rigidity of the heart comes on in most cases after, not before, death, and is a result, not cause, of death; that post-mortem rigidity is dependent upon coagulation of myosin, and that the rigidity of the heart is of similar origin, coagulation of the muscle-plasma occurring almost instantaneously at 115° F., a degree almost attained in sunstroke; that when a muscle has been in great activity immediately before death, myosin coagulates at a much lower temperature, and that the cases of sudden cardiac death occurring in battle among the East Indian English troops were no doubt due to the coagulation of the heart's myosin; that heating the brain of a mammal produces sudden insensibility, with or without convulsions, at a temperature of 108° F., and death when a temperature of 113° is reached; that this effect of the local application of heat is not due to induced congestion, but is the result of the direct action of the heat upon the cerebrum, and that consequently the nerve-centres are as perniciously affected by high temperature as the muscles are; that the nerve-trunks bear a temperature of 125° F. without their conducting power being immediately affected; that whilst the general symptoms induced by heating the brain of a rabbit are very different from those of sunstroke, the nervous symptoms are exactly similar; that the life of the blood is not destroyed by any temperature reached in sunstroke, the amœboid movements of the white blood-cells and the absorption power of the red disks not being injured; that the amount of oxygen of the blood is greatly lessened, as the result of gradual asphyxia combined with abnormal consumption of oxygen; that there is no reason for believing that capillary thrombi are common in sunstroke; that there is no specific poison developed in the blood; that the deterioration of the vital fluid is due to the rapid tissue-changes induced by the fever and the more or less complete arrest of excretion; that such deterioration is secondary to the nervous symptoms, not primary; that if the heat be withdrawn before it has produced permanent injury to the nervous system, blood, or other tissues, the convulsions and unconsciousness are immediately relieved and the animal recovers.

As a postulate from these facts and deductions, I think it follows that the nature of sunstroke is that of a fever; or, in other words, that *coup de soleil* is a fever, not dependent upon blood-poisoning, but upon heat.

It is of course possible that the external heat causes the fever, simply by preventing the body from throwing off the caloric which it is constantly forming. The extreme suddenness of the onset, however, indicates that in at least many cases there is a sudden outburst, as it were, in the production of heat in the body. This indication becomes more important when it is remembered that in cerebral rheumatism, so called, there is often an equally sudden attack of symptoms plainly the result of a sudden production of animal heat.

In an elaborate research¹ I showed the truth of Setschenow's theory, that there is in the pons a centre whose function it is to inhibit the production of animal heat, and that in the medulla a centre (probably the vaso-motor centre) which regulates the dissipation of the bodily heat; and that fever is due to disturbance of these centres, so that more heat is produced than normal, and proportionately less heat thrown off. Let it be supposed that a man is placed in such an atmosphere that he is unable to get rid of the heat which his body is forming. The temperature of his body will slowly rise, and he may suffer from a gradual thermic fever. If early or late in this condition the inhibitory heat-centre becomes exhausted by the effort which it has been making to control the formation of heat, or becomes paralyzed by the direct action of the excessive temperature already reached, then suddenly all tissues will begin to form heat with the utmost rapidity, the bodily temperature will rise with a bound, and the man drop over with some one of the forms of *coup de soleil*.

Under this view of the case the widespread popular belief, that protecting the back of the head and upper neck from the direct rays of the sun is useful against sunstroke, gains in significance, because it is possible that local heating of the parts spoken of may occur and aid in the production of inhibitory paralysis.

If this theory of thermic fever be correct, heat-exhaustion with lowered temperature probably represents a sudden vaso-motor palsy—*i. e.* a condition in which the exhausting effects of the heat paralyzes not the inhibitory heat-centre, but the vaso-motor centres in the medulla, since my experiments have shown that vaso-motor palsy increases enormously the loss of animal heat and diminishes its production.

In most cases of sunstroke death comes on gradually by arrest of respiration, such arrest being without doubt due to direct paralysis of the respiratory centres by the excess of heat. Allusion has already been made to the cases of sudden death by cardiac arrest, which have especially been seen in India, almost always during a march or during a battle. "As an example of it may be cited the account given by a witness to Parkes, and incorporated in his work on hygiene,² of an occurrence during the first Chinese war. The Ninety-eighth regiment was marching on a very hot day, and the surgeon who was with the rear-guard stated to Parkes that the men fell suddenly on their faces as though struck with lightning, and on his running up and turning them over many of them were already dead. Maclean, who was present at this occurrence, confirms the account given by Parkes, but states that it was at the attack on Chiang-Kiang-Foo. The men were thickly clothed, with tight accoutrements and tight, rigid stocks, and were charging up a very steep hill. A great

¹ *Fever*, Smithsonian Institute, 188-.

² *Pract. Hygiene*, 2d ed., p. 360.

number of them were stricken down, and fifteen died instantly, falling on their faces and giving merely a few convulsive gasps."

It has been shown that excessive exercise so alters the condition of the myosin of muscle as to cause it to coagulate much more readily than normal. During battle the amount of muscular effort that is made is enormous, and hence it is that men are so often found stiffened in the attitude in which they were struck by the bullet, instantaneous death being followed by equally instantaneous post-mortem rigidity. The description that has been given by Parkes and Maclean of the circumstances in which the sudden deaths just described occurred shows that the heart-muscles must have been strained to their utmost limit. The men were making violent exercise going up hill, so that the heart must have been in exceedingly active exertion, increased by the impediment to the circulation afforded by the tight accoutrements, and under these circumstances the victims probably died instantly because the heart-muscle suddenly set itself from life into the stiffness of death.

The DIAGNOSIS of thermic fever is usually made with great readiness. In distinguishing between it and heat-exhaustion the temperature of the body is the guide. In apoplexy with high temperature it is possible that a little embarrassment might be experienced, but in apoplexy the high temperature follows the nervous symptoms after a distinct interval, but in thermic fever it precedes the unconsciousness. An apoplexy may develop during a sunstroke, but such occurrence is rare. T. S—, now under my care, has had frequently repeated attacks of local convulsions affecting two fingers of the right hand, and one general epileptic attack whilst under observation. He dates his illness to a sunstroke on July 7, 1885, and O. D. Robinson of Georgetown, Delaware, writes me that the attack was undoubtedly true thermic fever, and that the movements of the fingers came on whilst the patient was recovering consciousness. It is probable, therefore, that there was a rupture of a small vessel in the brain-cortex during the sunstroke. The appearance of local convulsions or of localized paralysis during a sunstroke would be good ground for believing that either a clot or a thrombus had formed.

PROPHYLAXIS AND TREATMENT.—The prophylaxis of sunstroke is so evident in its nature that it may be dismissed in a few words. When exposure to heat is imperative the bodily health should be maintained by avoidance of alcoholic, sexual, or other excesses, and, as far as possible, of great bodily or mental fatigue; the diet should be almost purely farinaceous, and the glandular apparatus of the bowels, kidneys, and skin kept in an active state by the use of fruit, water in abundance, and mild salines if necessary. Many persons have a very strong prejudice against the drinking of cold water during exposure to heat; and it is conceivable that large draughts of intensely cold ice-water may do harm by suddenly chilling the stomach; but when the water is taken in small quantities at short intervals, by its action in reducing the general temperature, but especially by its rendering free perspiration more easy, it must exert a most favorable influence. The addition of claret or some other local stimulant to the water is often of great service when there is a tendency to gastric or intestinal depression.

In the mild cases of continued thermic fever the basis of the treatment should be the use of the cold bath. The plan adopted by Guiteras at Key

West was to wrap the patient in a dry sheet, lift him into a tub of water, having the temperature between 80° and 85° , and then rapidly cool this water by means of ice. The time of the immersion lasted from fifty to fifty-five minutes, it being regulated by the thermometer in the mouth of the patient. The patient was then lifted out upon a blanket, the skin partially dried, and the body covered. Guiteras found great advantage by giving a moderate dose of whiskey and thirty minims of the tincture of digitalis twenty minutes before the bath. He states that it is very important to avoid currents of air blowing upon the patient and to have the bath given in a small warm room. The result of the bath was invariably a lowering of the temperature, a reduction of the rate of pulse and respiration, and a refreshing sleep. After the second bath the course of the temperature seemed permanently influenced for the better. It was never necessary to give more than two baths in the twenty-four hours, but in some cases they had to be used for many days.

In the severe acute form of thermic fever it is essential that the bodily temperature be reduced at once, and no time should be lost waiting for a physician. As soon as the patient falls he should be carried into the shade with the least possible delay, his clothing removed, and cold affusions over the chest and body be practised. This must not be done timidly or grudgingly, but most freely. In many cases the best resort will be the neighboring pump. In the large cities of the United States during the hot weather hospital ambulances should be furnished with a medical attendant and with ice and antipyrin, so that when a sunstroke patient is reached he may be immediately stripped underneath the cover of the ambulance and remedial measures applied during his passage to the hospital. I believe many lives are now sacrificed by the loss of critical moments in the interval between the finding of the patient and his reaching the hospital ward.

If circumstances favor, instead of the cold affusions, rubbing with ice may be practised. The patient should be stripped and the whole body freely rubbed with large masses of ice. When practicable, a still better plan is to place the patient in the cold bath (50° F.) The employment of enemata of ice-water, as originally suggested by Parkes, may sometimes be opportune.

In using these various measures it must always be borne in mind that the indication is the reduction of temperature: if the means employed do not accomplish this, they do no good.

Relaxation of the pupil is said to be "the first symptom that shows the good of the cold affusion;"¹ but as, in my experience, the pupil frequently has not been contracted, reliance cannot be placed upon this, and the thermometer in the mouth or the rectum affords the only proper guide as to the effect of the treatment.

It must be borne in mind, however, that the cold douche, cold bathing, etc. are powerful remedies, and are capable, if used too long, of doing harm. In my experiments upon animals I have seen the temperature, when reduced by the cold bath after sunstroke, continue to fall, after the animal had been taken out of the water, until it was many degrees below normal.

In the cases which have come under my own observation after the use

¹ Aitken, *Practice of Medicine*, vol. ii. p. 394.

of the cold bath but little treatment has been required. If, however, the period of insensibility has lasted too long, there may be no return to consciousness, even though the bodily temperature be reduced to the norm. Under such circumstances the case is almost hopeless, and I know of no treatment other than that of meeting the symptoms as they arise, excepting that a large blister should, in my opinion, be applied to the whole of the shaved surface of the scalp.

After the temperature has been reduced, and even after consciousness has returned, there is sometimes a great tendency to a fresh rise of temperature, and consequent relapse. This tendency may be met by wrappings in wet sheets, and, if necessary, by a recourse to the more powerful measures for reduction of temperature which have been already cited. It can be to some extent controlled by the use of quinine, ten grains of which may be given hypodermically. During the heated term of the summer of 1885 antipyrin has been used both in New York¹ and in Philadelphia² with asserted most excellent results; and the testimony is so strong that I think it should always be employed as an aid to, not as a substitute for, the direct extraction of the bodily heat. It should be given hypodermically, as soon as the patient is found, in doses of from fifteen to thirty grains.

In cases complicated with repeated severe convulsions, hypodermic injections of one-quarter of a grain of morphia have been very frequently given in the Pennsylvania Hospital, with excellent results. In such patients the use of anæsthetics to facilitate the giving of cold baths would be very proper, but so long as the temperature is high nothing should be allowed to substitute the external cold.

Severe headache and other evidences of cerebral inflammation, manifesting themselves directly after the recovery of consciousness, should be met by local or even general bleeding, blistering, the use of arterial sedatives, mercurials, etc.; or, in other words, by the treatment of cerebral inflammation from other causes adapted to the exigencies of the individual case.

Formerly, venesection was largely practised in sunstroke, with occasional excellent effects, but with, on the whole, very bad results. As free bleeding lowers temperature markedly, it can be readily understood that in some cases it might bring about a return of consciousness and yet be a very improper remedy. If in any instance sthenic apoplectic symptoms persist after the lowering of the bodily temperature by the bath, venesection should be carefully considered. There are cases of sunstroke in which the high temperature irritates the brain or its membranes into an acute congestion or inflammation. These complications are especially prone to occur when the high temperature has been allowed to continue for a long time. A case of this character, in which the autopsy revealed proof of the presence of an acute meningitis, may be found on p. 121 of my book on *Thermic Fever*. When, then, the patient has a tendency to excessive headache and continuous fever, bleeding may become an essential remedy, not for the cure of thermic fever, but of the cerebral inflammation which has been produced by that fever. The case of S. Weir Mitchell is in point. In his early manhood he had a sunstroke, and when conscious-

¹ B. F. Westbrook, *New York Med. Journal*, July 25, 1883.

² Orville Horwitz, *Trans. College of Physicians of Philada.*, Oct., 1885.

ness began to return "the first sensation was that of an intense, agonizing headache, and the next was the perception of his father—J. K. Mitchell—and Mütter discussing the possibility of his recovery. As soon as he could speak, he said, 'Bleed me.' His father, coming to the bed, shook his head, but the son repeated, 'Bleed me.' He persisted in simply repeating this until they thought him delirious; but at last he mustered strength to say, 'I am not delirious, but have a frightful headache: if you don't bleed me I will die.' By this time his pulse had become full and bounding, and finally he sat up and was bled. Ten or fifteen ounces were taken without avail; but as more blood flowed the headache vanished, to be succeeded by a feeling of most delightful languor and rest from pain. Between twenty-five and thirty ounces were taken, and afterward recovery was a very simple matter."

That Mitchell by the bleeding was saved from meningitis appears almost certain, but it is most probable that if he had been primarily immersed in a cold bath no bleeding would have been required.

SEQUELÆ.—Almost all persons who have had a coup de soleil suffer from after-effects. In the mildest form these are inability to bear exposure to heat without cerebral distress or pain, with more or less marked failure of general vigor, dyspeptic symptoms, and other indications of disturbed innervation. In other cases the symptoms are more decided. Pain in the head is usually prominent: it may be almost constant for months, but is always subject to exacerbations. It sometimes seems to fill the whole cranium, but not rarely is fixed to one spot; and I have seen it associated with pain in the upper cervical spine and decided stiffness of the muscles of the neck. With it may be vertigo, decided failure of memory and of the power of fixing the attention, with excessive irritability. When the symptoms approach this point in severity, there is usually marked lowering of the general health, loss of strength, possibly some emaciation, and the peculiar invalid look produced by chronic disease.

Epileptic convulsions occasionally follow a sunstroke, but, at least in my experience, are always associated with more constant evidences of cerebral disease.

A pathognomonic symptom in the sequelæ of sunstroke is the effect of heat. The glare and heat of summer are the most trying, but usually artificial heat is not well borne. It is very common for headache and severe general distress to be produced by going into a warm room even in the winter months. Where cerebral symptoms are affirmed to be the result of a sunstroke, if there be no excessive susceptibility to heat the alleged sunstroke has almost certainly been an attack of some other nature; and on several occasions I have been enabled to determine that a supposed epileptic attack or a fall followed by unconsciousness from violence was really a sunstroke by noting the extreme susceptibility to heat. The symptom I believe to be a diagnostic one.

The lesion in these cases is usually chronic meningitis, though it is possible that in some instances the gray matter rather than the membrane of the brain may be affected, and in severe cases the gray matter is of course more or less compromised. In one case occurring in the care of S. Weir Mitchell, and in one in my own practice in which death occurred from extraneous causes, severe chronic meningitis was found at the autopsy.

The TREATMENT of these cases is that of chronic meningitis, with the added precautions against exposure to heat. In any severe case change of habitation to a cool climate during the hot period of the year is essential: twenty-four hours' exposure may undo all the good achieved by months of careful treatment.

It is hardly proper here to enter into a detailed discussion of the remedial measures to be employed in this as in the other forms of non-specific chronic meningitis. Local bleedings, the use of counter-irritation, especially by the actual cautery, the internal administration of mercurials and of iodide of potassium in small continued doses, with abstinence from brain-work and the regulation of the habits of life, constitute an array of measures which will no doubt be fully discussed by the author of the article upon Chronic Meningitis.

Provided the patient can be entirely controlled, the PROGNOSIS in these cases is not so bad as at first it appears to be. As an instance of a remarkable recovery I condense from my notebook the case of T. W. H—, aged 49, who came under my care with a history that two years previously he had been seized during a hot day in the summer with a very violent headache, which continued for five weeks, confining him to bed, and was associated, as he said, with fever, but no other symptoms. This attack had been diagnosed by several physicians variously, but as I found that he was excessively affected by any exposure to the sun, was always worse in summer, and that in winter his symptoms were extremely exaggerated even by such heat in a room as is agreeable to many persons, I concluded that the original attack had really been one of thermic fever. He had lost about forty pounds in weight; his memory had become so bad for recent events that he could not call to mind things which had transpired one or two hours previously. Sight had failed much, and there was double vision. He suffered from almost incessant dull headache and excessive general wretchedness; the optic discs were slightly swollen, and one of the margins obscured. There was no albuminuria, and the dyspeptic symptoms were so bad that the man had been treated for months for dyspepsia. Nine months of treatment sufficed to restore this patient almost to his original health. The treatment consisted essentially in the alternate administration of minute doses of calomel and of iodide of potassium—in the meeting of various minor symptoms as they arose, but chiefly in the persistent, merciless use of counter-irritation at the nape of the neck. The actual cautery was applied every one or two weeks, and antimonial ointment freely used on the burnt surface.

HEADACHE.

BY WHARTON SINKLER, M. D.

SYNONYMS.—Cephalalgia, Cephalœa.

It is not possible to give in a few pages a complete treatise on headache, and it is therefore intended merely to describe the most common types of this malady.

Many forms of headache are symptomatic of some organic cerebral disease, like tumor of the brain or syphilitic diseases of the skull. Headache also constantly accompanies fevers of all kinds. A great number of cases are met with in which no cause for the headache can be discovered, and in which the pain is the only symptom. In these there must be some disordered state of the sensory nerves within the cranium, but just what the nature of the abnormal condition is it is impossible to decide.

The character of the pain in headaches is various. In some cases there is a violent general pain over the entire head. In others the pain is localized in one particular spot, feeling as if a nail were being driven into the skull. This is called *clavus*, and is often met with in hysterical patients.

Patients sometimes describe the head as feeling as if it were splitting open, or, again, as if it were being compressed. The pain may involve one side of the head alone, *hemisrania*, or it may be only in the back of the head. The top of the head is a frequent seat of pain, especially in women who have uterine disorders. In short, the pain may be in any or every portion of the head, or it may move about from place to place.

In almost all varieties of headache the pain is aggravated by noises or strong light. Any movements of the patient increase it, and coughing, sneezing, or straining—as, for instance, at stool—adds to the suffering. Tapping on the head usually does not increase the pain, and in some instances alleviates it.

Accompanying the headache is a variety of other symptoms: some of them are nervous, while others are not. There are often disturbances of vision, such as bright spots or zigzags before the eyes; and there may be ringing in the ears; palpitation or slowing of the heart. Nausea occurs in most varieties of headache, and a feeling of general prostration or nervous excitability is often experienced both during and after an attack.

The duration of an attack of headache varies from a few minutes to

days or even months: one occasionally sees a patient who says she has not known what it is to have been without pain in the head for years.

The character of the pain may be either a dull aching or it may be excessively intense, so as to cause temporary aberration of mind. As to the structures within the cranium in which the pain is located, it is a mooted question. Some writers believe the dura mater may be the seat of pain in headaches, while other observers have declared this membrane to be insensitive. Probably the intracranial branches of the fifth pair of nerves are the principal site of pain.

We will now consider particularly the different varieties of headache most commonly met with.

ANÆMIC HEADACHE.—The pain is of a dull kind, often diffused over the head, but frequently in the vertex or temples. It occurs in weak, thin-blooded persons, and is relieved by the recumbent position. If the patient is sitting or walking, the pain becomes worse, and there is a sense of faintness or dizziness. Women are the most common sufferers from this form of cephalalgia, and uterine diseases or disorders of menstruation are connected with it. It is associated with palpitations of the heart, difficulty of breathing, a tendency to faint, and general weakness. Anything which exhausts the nervous system, like over-study or anxiety, loss of rest and sleep, is likely to bring on an attack.

CONGESTIVE (HYPERÆMIC) HEADACHE.—In this variety of headache, which is common, the pain seems to affect the whole head and is of a dull, throbbing character. The recumbent position aggravates it, as does coughing or straining. During the paroxysm the face is flushed, the eyes suffused, and the arteries throb violently. Sleep relieves the pain of a hyperæmic headache for a time, but as soon as the patient begins to move about, or even to exercise the mind, the pain returns. Erb¹ speaks of a violent pain in the brow and temple, with a sense of pressure and fulness in the head, and heat and redness in the face and ears. This form may come in regular paroxysms. He has seen one case of this kind in which there was violent pain accompanied by fainting, and intense redness of the brow and vertex was observed.

THE HEADACHE OF HYSTERIA is usually seen in females, although it may occur in males. It is sometimes general throughout the head, but is often located in one spot (*clavus*), and is very intense. The seat of *clavus hystericus* is at the top of the head to one side of the sagittal suture. The pain is described as boring, gnawing, and burning. The headache is more severe at the menstrual period, and is increased by worry or trivial excitement. Nervous and hysterical subjects complain of headache which never ceases.

TOXIC HEADACHES are the result of the introduction into the system of various kinds of poisons. The headache following alcoholic excesses is a well-known instance of this kind. The pain, which is deep-seated and often intense, is supposed to be in the sensory nerves of the dura mater. Other forms of chronic poisoning give rise to headache. Lead, when retained in the system, produces headache, and so do many of the narcotic drugs. In some persons the administration of iron always causes pain in the head. The headache following a dose of opium is familiar to all. The excessive use of tobacco is often followed by dull headache next

¹ *Cyclopædia of the Practice of Medicine* (Ziemssen), vol. xiv. p. 140.

day. The intense pain in the head caused by uræmic poisoning is a well-marked symptom of this condition. Seguin has lately well described the headache of uræmia.¹

RHEUMATIC HEADACHE is often violent, and the pain seems to be located in the head-muscles. It occurs in rheumatic subjects. It is brought on by exposure to cold, and is increased by damp changes in the weather. In acute rheumatism there are sometimes met with attacks of intense headache. Headache also is associated with the gouty cachexia, and is accompanied usually by depression of spirits and sometimes vertigo.

PYREXIAL HEADACHES.—In all of the acute fevers headache is a prominent initial symptom, and usually continues throughout the course of the disease. The pain is generally dull and deep-seated, and is probably congestive in character. The headache of typhoid fever is constant, and often precedes the fever by many days. Following an attack of typhoid fever, it is not infrequent to find headache persisting for months or even for years.

SYPHILITIC HEADACHE is one of the most violent forms of headache. The pain is diffused or limited to one part of the head, and is associated with tenderness of the scalp. It becomes most severe at night, but never entirely intermits. The nocturnal exacerbations, although very common, do not always occur. The pain is so violent and so constant that the patient is unable to do any work or to occupy himself in any way. There is great mental depression, and the patient becomes gloomy and morose. The pain may be dull and heavy or acute and lancinating; sometimes it is like a succession of heavy blows on the skull. During a severe paroxysm of pain the scalp becomes so sensitive that the lightest touch cannot be borne. The sufferer is unable to sleep, and presents a worn, haggard appearance. Often he has hallucinations at night. Syphilitic headache is often a forerunner of some form of organic cerebral disease. One of the characteristic features of syphilitic headache is its constancy. It never ceases entirely, although at times there are paroxysms in which the pain is so intense as to cause great agony. During the little sleep the patient is able to get he is moaning or tossing about his bed. Minute doses of mercury, repeated at short intervals, have been found to afford great relief in headaches of this kind.

ORGANIC HEADACHE may be described as the headache which accompanies organic disease of the brain or its membranes. Violent pain, seated in one spot and constant in character, is one of the most unvarying symptoms of tumors within the cranium. Brain tumors may exist without headache, but rarely. The pain may be situated in any part of the head: sometimes it is occipital and sometimes frontal, and occasionally it extends over the entire head. It does not always correspond to the seat of the disease. The pain is constant and lasting, and, like syphilitic headache, is liable to exacerbations of excessive violence. These often occur at night. Localized tenderness of the scalp is often present, and percutting the skull over the seat of the disease will increase the pain.

Disease of the membranes of the brain, such as meningitis or new growths in the dura mater, will give rise to persistent headache. So will

¹ *Archives of Medicine*, vol. iv. p. 102.

caries or any syphilitic affections of the skull. Catarrhal inflammation of the frontal sinuses causes dull frontal pain. In inflammatory diseases of the ear there is often headache. In these latter conditions the cephalalgia is probably reflex.

NEURASTHENIC HEADACHE is more or less allied to the hysterical headache. It is met with in persons who are run down in their nervous system by mental worry or overwork—in other words, in persons who are suffering from neurasthenia. Such patients describe the pain as being constant and deep-seated—seldom acute, but dull and throbbing. It is accompanied by a sense of weight and pressure on the vertex, and sometimes by a feeling of constriction. Mental effort increases the pain, and the patient usually prefers solitude and quiet on account of the relief he obtains. The headache of neurasthenia often persists after other symptoms of the affection have disappeared.

SYMPATHETIC HEADACHE is generally connected with disorders of the digestive and sexual organs. The headache of ovarian disease is well known to gynecologists, and most of us have experienced the pain in the head associated with gastric disturbances. The headache from eye-strain may be considered in this connection, and deserves careful consideration. Many persons have suffered from headaches for years from this cause without its being suspected. Weir Mitchell brought prominently to notice the frequency with which headaches may be caused by defects of vision.¹ The fact had been long known to oculists that disorders of the refractive apparatus of the eye would give rise to cerebral discomfort and pain, but it had not before occurred to physicians to look to defects of the eye to explain headaches whose cause was obscure. The points made by Mitchell were—1, that many headaches are caused indirectly by defects of refraction or accommodation; 2, that in these instances the brain symptom is often the only prominent symptom of the eye trouble, so that there may be no ocular pain, but the strain of the eye-muscles is expressed solely in frontal or occipital headache; 3, that long-continued eye troubles may be the unsuspected cause of insomnia, vertigo, and nausea; 4, that in many cases the eye trouble becomes suddenly injurious, owing to break-down in the general health or to increased sensitiveness of the brain from mental or moral causes.

Occasionally the form of headache produced by eye-strain is a migraine, but most commonly there is a steady frontal or occipital pain, which comes on after undue use of the eyes, which are defective as to refraction or accommodation. Accompanying the pain are sometimes nausea and occasionally vertigo. It is not only over-use of astigmatic eyes in reading or other near work which causes the cerebral disorders, but the use of the eyes in the ordinary walks of life may produce pain in a sensitive brain should there be any imperfection in refraction or accommodation.

HEADACHE FROM SUNSTROKE.—A person who has had an attack of sunstroke often suffers from headache for years. The attacks are most likely to occur from exposure to the sun and in summer months, but they are brought on in some individuals even in winter should they be in the sun. Sometimes heat-exhaustion or exposure to the influence of the sun in hot weather, even should there be no actual sunstroke, is

¹ *Med. and Surg. Reporter*, Aug. 1, 1874, and *Amer. Journ. of the Med. Sci.*, April, 1876.

followed for a long time by violent headaches. Persons who have suffered in this way have to be extremely careful about exposing themselves to the sun or they will have severe and prostrating pains in the head. The cephalalgia in these cases is probably from congestion of the cerebral meninges or some disturbance of the submeningeal gray matter of the brain. The pain is usually frontal or on the top of the head. Sometimes it is confined to one side of the head. Mitchell¹ has seen two cases in which this form of headache was relieved by ligature of the temporal arteries.

HEADACHE OF CHILDHOOD.—Children often suffer from headaches unconnected with meningitis or other organic brain trouble. Over-use of the brain in study is a frequent source of headache, in children especially, if associated with worry or anxiety. If a child complains of headache after study, it is always important to examine the eyes for defects of vision; but while this is often found to be the cause of the headache, in many cases there will be discovered no errors of refraction sufficient to account for the pain; and here the only relief will be to take the child from school and give him plenty of exercise and fresh air.

Another cause of headaches in children is hypertrophied tonsils, which prevent the free return of blood from the brain. Children also suffer from headaches from over-eating or improper food, or from over-exercise in the sun. Migraine, as will be seen later, is a disease which often begins in early childhood, and a child may suffer from frequent attacks of headache of this nature for a long time before they are understood.

Children who are precocious in any way are apt to be sufferers from neuralgias and headaches; but sexual precocity especially predisposes to headaches of the type of migraine. Anstie² goes so far as to say that the existence of a severe neuralgic affection in a young child, if it be not due to tubercle or to other organic brain disease, is, *primâ facie*, ground for suspecting precocious sexual irritation.

Hillier³ observes that anæmic children from seven to ten years of age frequently suffer from neuralgic headache, and that girls between eight and twelve have violent headaches accompanied by nausea and vomiting (migraine).

HEADACHE FROM DYSPEPSIA.—Persons who have indigestion have more or less headache, either in paroxysms or as a constant pain. The pain is either frontal or occipital, and may affect the whole head; but it is not confined to one side of the head, as in migraine. The pain is usually dull, and is accompanied by nausea from the beginning of the attack. The tongue is coated, and has red edges, and there are general evidences of gastric disturbance, together with a history of some indiscretion in diet. Sleeping does not always relieve the headache.

DIAGNOSIS.—The diagnosis of the different forms of headache may be made by considering the symptoms. All of the means at our command should be used to carefully distinguish the variety of headache we have to deal with. The head should be palpated for tender or swollen and soft spots, such as are found often in syphilitic headaches. Sometimes percussion of the head will give us some indications as to the kind of

¹ *Med. and Surg. Reporter*, July 25, 1874.

² *Neuralgia and Diseases that Resemble it*, p. 31.

³ *Diseases of Children*, p. 194.

headache which exists. The eyes should be examined ophthalmoscopically for changes in the fundus oculi, and the vision should be tested for errors of refraction should there be any reason to connect the pain with the use of the eyes. Inquiry into the habits, occupation, and family history of the patient will aid in arriving at a correct diagnosis.

TREATMENT.—Having reached a correct diagnosis, the treatment will naturally be directed to the special form of headache with which we have to deal. The indications vary more or less with the different varieties, but in all the same object is in view; that is, the relief of pain in the paroxysms, and the breaking up of the diseased condition which leads to the attacks. The means to be used for the former will be considered in the treatment of Migraine, and are more or less applicable to the treatment of all forms of headache.

In children, if no ocular cause is present, it will often be necessary to take them from school and study, and make them take plenty of exercise in the fresh air.

In all varieties of cephalalgia change of climate and travel exert a most beneficial influence. The seashore does not always benefit sufferers from headache, and sometimes the sea air seems to increase the pain.

Migraine.

SYNONYMS.—Hemicrania, Sick headache.

This form of headache is of great importance, from the frequency with which it is met in practice. It occurs in paroxysms at longer or shorter intervals, but the attacks come at periods of tolerable regularity, and, generally speaking, the intervals are entirely free from pain. From the name hemicrania it may be inferred that the pain is confined to one side of the head. This is often the case, but is not invariably the rule.

Migraine has been known for many years, and the term hemicrania is used by the old writers. Until recently, however, there has been some confusion regarding it. Hemicrania often meant trigeminal neuralgia, and nervous sick headache was generally believed to have its origin in the stomach or to be the result of biliousness. Of late years the disease has come to be better understood, and the valuable works of Liveing, Anstie, and others have given a full literature of the subject.

Various conditions predispose to migraine, and of these the foremost are period of life and hereditary influence. Sex also bears a part in the etiology. The majority of patients who are victims of migraine are females. Eulenburg¹ states that the proportion is about 5 to 1 in favor of females. My own experience would lead me to believe that in this country the preponderance of migraine in females is not so great. Men are not so likely to consult a physician about headaches, unless they become very frequent and severe; especially is this true of the laboring classes, from whom Eulenburg's statistics were mainly taken. It is true that women are especially prone to neuroses of various kinds through menstrual disorders and at the time of the climacteric, but these do not always take the form of migraine.

Age has a decided influence on the production of migraine. Sometimes

¹ *Ziemssen's Cyclopædia*, vol. xiv. p. 5.

the attacks begin in very young children. Eulenburg mentions cases at four or five years. It is during the period of bodily development that the first outbreaks of migraine occur, but more particularly do they set in in both sexes at puberty, a time when sexual development is active and making a strong impression on the whole nervous system. Should migraine become established at this time, it will probably continue to harass the individual until he is forty-five or fifty years of age. After the development of puberty migraine is not likely to originate; indeed, Tissot¹ declares that a person who is not attacked by migraine before his twenty-fifth year will escape from it for the rest of his life. It certainly is the case that in later life this affection is much more rare than earlier, as many of the old cases get well and new ones scarcely ever develop. It is a common thing to hear a patient who has reached the age of fifty extolling some new system or remedy as a cure for his headaches, from which he has suffered all his life, when in reality the attacks have ceased or become infrequent on account of the natural course of the disease.

Hereditation markedly affects the production of migraine. Eulenburg states that it follows the female line, and is inherited from the mother only; but this is surely a mistake, as we often see males whose fathers suffered from migraine. Persons whose ancestors were of a neurotic type, who suffered from neuralgias, paralysis, hysteria, insanity, etc., are particularly liable to migraine. Epilepsy is also likely to be in the family of an individual who has migraine. There has been observed by many writers the association of migraine and epilepsy in the same person. Epileptics who are predisposed to the disease by inheritance are likely to have attacks of it preceding the outbreak of epilepsy. In families of constitutional nervous tendencies it is common to see certain members who have hemicrania, while others have epilepsy or are insane.

Other predisposing causes in migraine are not so marked as those already mentioned. Station in life exerts but little influence in the causation of the disease. It is met with as often in the laboring classes as in the wealthy. Those who use the brain to any extent in study or business are likely to suffer more often from migraine than those who lead an outdoor life with much physical exercise. Habitual loss of sleep and anxiety also predispose to it.

As to the conditions connected with the immediate production of an attack of migraine, we are in ignorance. It has been thought to depend upon disorders in the circulation of the blood, but then the question arises, Whence these disturbances of circulation? Probably those circulatory disorders which are marked in every case are effect rather than cause of the attack. Indigestion and biliousness must be admitted to favor outbreaks of migraine.

SYMPTOMS.—Migraine occurs at intervals of one or two weeks or longer; often the attacks are not more frequent than every month or even two or three months. I have seen a number of patients who have attacks of migraine on Sunday with regularity, and escape during the interval. Some of these cases ascribed the attacks to sleeping later on this day than on others, but it is more likely that the attacks were the result of the culminating effect of a week's hard work. Between the attacks the patient is usually quite well as far as headache is concerned,

¹ Quoted by Eulenburg, *op. cit.*

but he may have slight neuralgia in branches of the trigeminal. The attacks are more or less alike. They are often preceded by prodromal symptoms for a day or two. The patient may feel languid or tired for a day before the attack. Sometimes there is unusual hunger the night before a paroxysm, or there may be violent gastralgia before each attack. The patient often wakes in the morning after sound sleep with a pain in the head. Should the attack come on in the day, it may be preceded by chilliness, yawning, or sneezing and a sense of general malaise. Ocular symptoms are frequent as a forerunner of an attack. First *muscae volitantes* are seen, then balls of fire or bright zigzags appear before the eyes, making it impossible for the patient to read. These symptoms last for a few minutes or a half hour, and then cease, to be immediately followed by pain. Hemianopsia is a precursory symptom of rather frequent occurrence. Ross mentions a case in which the hemianopsia usually lasted about a half hour, and was followed by severe hemicrania. The ocular symptoms are often very alarming to patients.

The pain, as a general rule, is at first in the ophthalmic division of the fifth nerve and its branches. It may begin in the branches of the occipital nerve or in the parietal region. It comes on gradually, is dull and boring at first, but becomes more intense and spreads to one lateral half of the head, more especially the front part. As it increases in intensity the pain seems to involve the entire head. Either side of the head may be affected. Eulenburg thinks that the left side is attacked twice as often as the right. An individual may have the pain on opposite sides of the head alternately in different attacks. The pain is described by patients as dull and boring or intense, and the head feeling as if it would burst. Patients often make pressure on the head to obtain relief. At times the pain seems to be of a violent, throbbing kind, keeping time, as it were, with the pulsation of the arteries. Lying down usually relieves the pain, but if it is violent the recumbent position seems to favor the afflux of blood to the head, and thereby increases the pain. The eye of the affected side becomes bloodshot, and the tears stream from it. The eyelid droops, and the sight is dim and clouded or may fail entirely. The least light is unbearable. During the attack the subject is chilly and intensely depressed, and the feet are very cold. The pulse is at first slow, small, and compressible.

Painful points (Valleix's points) are not present, but there is usually tenderness over the supraorbital notch during an attack of migraine, and after the paroxysm there is a general soreness of the scalp and forehead. Sometimes there remains a tenderness of the parts surrounding the affected nerve. This is not in the nerve itself, but in the adjacent tissues. Anstie¹ says that in his own case, after repeated attacks of migraine, the bone had become sensibly thickened in the neighborhood of the supraorbital notch. There is sometimes hyperæsthesia of the skin in the affected regions of the forehead and scalp during an attack. As well as hyperæsthesia, there may be an abnormal acuteness of the sense of touch. Deep pressure over the superior and middle ganglia of the sympathetic causes pain, according to Eulenburg. This observer also states that the spinal processes of the lower cervical and upper dorsal vertebræ are painful on pressure.

¹ *Op. cit.*, p. 182.

During the attack of migraine there is complete loss of appetite, and any food that may be taken remains undigested in the stomach for hours. As the pain intensifies there comes on a sense of nausea, there is a profuse flow of saliva, and large quantities of limpid urine are passed. Finally, when the pain seems to have reached its maximum, vomiting occurs. Immediately afterward the pain is greatly increased, but this is the result of the increased amount of blood in the cranial cavity from straining. Soon after, the patient is easier, and falls into a sleep, from which he awakes free from headache. The crisis is not always accompanied by vomiting. In some instances there is no nausea, but at the acme of the pain there are two or three profuse diarrhœic stools, after which the pain is relieved. I have lately seen such a case in a young man of twenty-three years of age. Sometimes there is only a profuse sweat or large flow of urine.

During the attack there are disorders of the circulation. The pulse may be intermittent or irregular, and the extremities are usually cold. Disorders of cutaneous sensibility are also often present. A condition of numbness confined to one lateral half of the body is sometimes experienced during the early part of the paroxysm. This numbness is noticed even in one half of the tongue.

The German writers have divided migraine into two types, and the arrangement may be followed in some instances. The first is called *hemierania spastica* or *sympathico-tonica*. In this form there is supposed to be vascular spasm and a diminished supply of blood in the brain. The symptoms are as follows: When the attack has reached its height the face is pale and sunken; the eye is hollow and the pupil dilated; the arteries are tense and feel like a cord. The external ear and the tip of the nose are cold. Eulenburg¹ states that by actual measurement he has found the temperature in the external auditory meatus fall 0.4° to 0.6° C. The pain is increased by stooping, straining, or anything which adds to the blood-supply in the head. At the end of the attack the face becomes flushed and there is a sense of heat. The conjunctiva becomes reddened, the eye is suffused, and the pupil, which had been dilated, contracts. The sense of warmth becomes general, the pulse is quickened, and the heart palpitates. The crisis is reached with vomiting and a copious flow of urine or perhaps a diarrhœic stool. There is sometimes an abundant flow of saliva. One observer has reported that he has estimated a flow of two pounds of saliva during an attack.

The other variety is termed *hemierania angio-paralytica* or *neuro-paralytica*. Here we find the opposite condition of things from that met with in *hemierania spastica*. There is marked increase in the amount of blood in the brain. When the attack is at its height the face on the affected side is flushed deeply, hot, and turgid. The conjunctiva is injected, the lachrymal secretion increased, and the pupil contracted. Sometimes there is slight ptosis. The ear on the affected side is hot and red. The temperature of the meatus may rise 0.2° to 0.4° C. The temporal artery is swollen, and throbs with increased force. The carotid beats visibly. There is free perspiration, which is sometimes unilateral. Compression of the carotid on the painful side relieves the pain, while pressing on the opposite carotid makes it worse. The heart beats

¹ *Op. cit.*

slowly, the pulse being sometimes as low as 48 to 56. At the end of the attack the face becomes paler and the other symptoms subside.

There are many cases in which the vascular conditions present no peculiarities during the attack, and which cannot be classed with either of the varieties just described.

In all forms, if the patient can be quiet, he usually falls asleep after the crisis has been reached, and awakes free from pain, but feeling haggard and prostrated.

The paroxysm lasts for several hours, generally the greater part of the day. It may last for several days, with variations of severity. The attacks are at longer or shorter intervals of time, and in women they often appear at the menstrual period. The attack may be brought on by over-mental or bodily exertion, imprudence in eating or drinking, and exposure to cold draughts of air. It will often begin as a supraorbital neuralgia from exposure to cold, and go on through all the phenomena of a regular migraine.

Seizures are often brought on by fatigue, and there are some persons who invariably have a violent attack of migraine after a journey. Nursing women are liable to more frequent paroxysms, and I have recently seen a lady who within a few days after delivery after both of her confinements suffered from typical attacks of migraine, although during gestation she had escaped them.

DIAGNOSIS.—Migraine can readily be distinguished from the other forms of headache by the comparative regularity of the attacks and its numerous other characteristics. It differs from neuralgia in the pain being less acute and shooting. The pain of migraine is more dull and throbbing, and extends more generally over the head. The ocular phenomena are more or less constant in migraine and do not occur in neuralgia.

PROGNOSIS.—Migraine is never fatal, and usually becomes less severe and less frequent as middle life is reached. Some patients continue to suffer from it during their entire life, and often when the typical migraine has ceased it is replaced with paroxysms of neuralgia. Therapeutic and hygienic means are of decided influence in the course of the disorder, and many patients experience great relief or temporary immunity from attacks as a result of treatment. Cases of long standing and those of an hereditary type are most unfavorable as to relief from treatment or by spontaneous cure.

PATHOLOGY AND MORBID ANATOMY.—Migraine not being a fatal disease, we know nothing of the changes which exist in the brain; we can only surmise what are the conditions which exist in the brain during and before an attack.

It is evident that there is a strong relationship between migraine and neuralgia of the trigeminal nerve, and if we study the symptoms of the two conditions, and consider the causes which produce attacks of each, we cannot but arrive at the conclusion that migraine is a variety of a neuralgia of the ophthalmic division of the fifth. The late Anstie has most clearly and forcibly given his reasons for believing this to be the case, and we cannot but uphold his view.

Migraine is constantly met with in early life as the type of a neuralgia which in later years loses the special features of a sick headache and becomes

a pure neuralgia. The same forms of trophic lesions may occur in migraine and in trigeminal neuralgia. Anstie instances his own case, in which in early life he had distinct attacks of migraine, with corneal ulceration, orbital periostitis, and obstruction of the nasal duct, while later in life his attacks were only neuralgic, without any stomach complications.

Migraine, as already remarked, attacks early life especially at the time of sexual development, and the same is true of epilepsy. There is also the same hereditary predisposition to the former as to the latter. Patients who have migraine belong often to families other members of which suffer from epilepsy, chorea, and an uncontrollable tendency to alcoholic excesses. Indeed, occasionally migraine and epilepsy are interchangeable in the same individual. Many cases of epilepsy have suffered at some time of their lives from severe headaches.

Hughlings-Jackson describes the attacks of migraine as arising from a discharging lesion of the cortex of the brain in the sensory area, or in that part of it which corresponds to the region of pain in the head. Genuine epilepsy he holds to be due to a discharging lesion from the motor area of the cortex. During an attack of migraine the discharging lesion does not remain confined in the sensory portion of the cortex, but extends into the medulla oblongata and the cilio-spinal region of the cord, causing irritation or paralysis of some of these centres, and causing the vaso-motor and oculo-pupillary symptoms which are conspicuous during an attack.

In the form of migraine known as *hemicrania sympathico-tonica* there is tonic spasm of the vessels of one side of the head. This explains the pallid face, the lowered temperature, and the sunken eyes. After the cause of the contraction is removed, then the vessels relax and the amount of blood-supply greatly increases. Hence the redness of the conjunctiva, lachrymation, and redness of the ear at the close of an attack. The vomiting is explained by Eulenburg as being due to variations in the intracranial blood-pressure. This causes fitful contractions of the vascular muscles, alternating with partial relaxation. These conditions must arise in the sympathetic nerve of the corresponding side.

The dilation of the pupil during an attack depends upon irritation of the cervical sympathetic ganglia. Other symptoms, such as the largely increased flow of saliva and the flow of tears or drying of the Schneiderian mucous membrane, indicate a morbid condition of the cervical sympathetic. The sensitiveness to pressure in the region of the upper cervical ganglia and over the spinous processes of the lower cervical and upper dorsal vertebræ, corresponding to the cilio-spinal region of the cord, confirms the idea of a morbid state of the cervical sympathetic.

In *hemicrania angio-paralytica* there is supposed to be a relaxed condition of the vessels of one side of the head. Here, instead of an irritation of the sympathetic, there is a paralytic condition, and we have the same results as are seen in animals when the cervical sympathetic is divided. There seem to be good grounds for holding this view when we consider the flushed face, contracted pupil, retraction of the eyeball, and occasional ptosis which accompany this form of headache. Possibly there may be a brief stage of spasm of the vessels preceding the relaxation which occurs in *hemicrania angio-paralytica*.

The slowing of the pulse during an attack of migraine is due probably to cerebral hyperemia from relaxation of the vessels, or to the secondary anæmia and irritation of the medulla oblongata. This irritation of the medulla is also able to explain the other symptoms of vaso-motor disturbance which occur during an attack of migraine; for instance, the small and contracted radial artery, the extreme coldness of the hands and feet, and the suppression of perspiration over the whole body except perhaps on the affected side of the head. Following the stage of irritation of the medulla with contraction of the vessels comes one of exhaustion with relaxation of the vessels. This latter state may account for the profuse flow of saliva and the copious secretion of sweat and urine, as well as the increased secretion of bile and the condition of bronchotracheal catarrh during the attack.

We now come to the question of the origin and seat of the pain in migraine. This question has involved a great deal of thought, and has been answered in various ways by different writers. E. du Bois-Raymond thought that the pain was due to tonic spasm of the muscular coats of the vessels, and that thereby the nerves in the sheaths of the vessels were pinched, as it were, and so caused pain. Moellendorff was of the opinion that the pain was due to dilatation of the vessels, and not to contraction; and this theory might explain the pain in the angio-paralytic form. There are many cases in which neither of these views is sufficient, for we have no reason to believe that a condition of either anæmia or hyperæmia is present.

Romberg believed that the pain was situated in the brain itself, and Eulenburg holds that the pain must be caused by alterations in the blood-supply, without regard to their origin, in the vessels of one side of the head. He thinks that the vessels may contract and dilate with suddenness, just as is often seen in some neuralgias, and thus intensely excite the nerves of sensation which accompany the vessels. The increase of pain upon stooping, straining, or coughing, and the influence upon it by compression of the carotids, seem to give force to this view. But are we not here confusing cause with effect? Are not these variations in the calibre of the vessels due to the irritation of the sensory and vaso-motor nerves, which are in a state of pain? No doubt increase in the blood-supply augments the pain, just as it does in an inflamed part when more blood goes to the part. Let a finger with felon hang down, or let a gouty foot rest upon the floor, what an intensity of pain follows!

Anstie very ably advocated the theory of migraine being a variety of trigeminal neuralgia in the ophthalmic division; and we incline strongly to his view. An attack of migraine often begins with pain distinctly located in the supraorbital nerve as the result of exposure to cold. Frequently it begins in the infraorbital nerve or in the branches of the inferior maxillary division of the fifth. The pain then spreads over one side of the head, both outside and inside, and goes through the recognized symptoms of migraine. In my own case I have often had an attack begin with sharp pain in the supraorbital notch in a spot which could be covered by the tip of the finger. The nerve has seemed swollen, and has been highly sensitive to pressure. Then have come pain extending over the entire side of the head, without its limits being distinctly definable, and the accompanying phenomena of lachrymation, excessive salivation,

and copious flow of urine, winding up with vomiting or ineffectual nausea and retching.

Anstie brings forward as arguments to support his view the facts that the attacks of migraine often interchange with neuralgic seizures, and that a person who has been migraineuse in early life may in later years lose his hemicranial attacks, and have violent neuralgia in the ophthalmic division of the fifth nerve.

The true seat of the lesion, if we may so call it, upon which the exaggeration of pain-sense depends, is probably in the nerve-centre; that is, in that part of the trigeminal nucleus back to which the fibres go which are distributed to the painful areas. The pain is no doubt chiefly intracranial, and in those portions of the cerebral mass and meninges to which branches of the trigeminal are distributed. All of the divisions of the trigeminus send branches to the dura mater. Many nerves are found in the pia mater as plexuses around the vessels, some of which penetrate into the centre of the brain. Most of these nerves come from branches of the trigeminus.

TREATMENT.—The treatment of migraine must be directed to the palliation of the attacks and to their prevention. So little is known of the direct cause of the disease that it is difficult to lay out any distinct course to be followed. Many cases, however, which seem to depend upon a run-down state of the patient are vastly improved by a course of tonics and building up. I have often seen anæmic and feeble women whose attacks were frequent become exempt for a long period by simply taking iron, quinine, and strychnia, and taking an increased amount of nourishment. The rest-treatment of Weir Mitchell is particularly applicable to these cases. In persons whose digestion is bad, and who suffer from constipation, much can be done by relieving these conditions. Some cases which are due to uterine disturbances are benefited by treatment directed to the womb. There are many cases, however, in which no cause is apparent. The patient is well nourished, his eyes are good, he undergoes no strain mentally, morally, or physically, and yet the attacks of migraine come with tolerable regularity. In these persons change of climate sometimes works marvellously beneficial results. I saw last year a young lady who suffered from terrific headaches which sometimes lasted for days. No plan of treatment or regimen seemed to exert the slightest influence upon the attacks, and yet on going to the far West for the summer she remained without an attack during the whole time she was there. In some individuals all forms of treatment may be tried in vain. Anti-periodics have been tested, but with doubtful benefit. *Cannabis indica* is probably the most potent remedy which is at our command. Its effects are most decided, and many cases of severe hemicrania have been cured by this means alone. It must be given for a long time, and in some instances it is necessary to give gradually-increasing doses up to the physiological effects. The drug must be of good quality, otherwise we need expect no good from it. Indian hemp is well known to be variable in strength, and the best form in which to use it is a fluid extract made by some reliable chemist. Arsenic, phosphorus, and strychnia do not seem to do as much good as in other neuralgias, except so far as they build up the general health.

Ergot has been used with success as a curative means, and it probably

acts by contracting the vessels of the medulla oblongata. A combination of ergotin and extract of *cannabis indica* may be given together; and if persisted in for a long time will often be of benefit in lessening the frequency of the attacks. The prolonged use of one of the bromides is sometimes found curative.

Anstie has found the careful use of galvanism to the head and sympathetic of positive advantage in keeping off attacks, and Eulenburg has had the same experience.

In the treatment of the attack the patient should be freed from all sources of external irritation. He should lie down in a darkened room, and all noises should be excluded. If the attack is of the hyperæmic variety, the patient's head should not be low, as this must favor increase of blood to the head. In this form the patient is often more comfortable sitting up or walking about. Occasionally an impending attack can be warded off by the administration of caffeine, guarana, or *cannabis indica*. Purgatives are of but little value in this form of headache. The local application of menthol or of the oleate of aconitia to the brow of the affected side will sometimes prevent an attack. If a person can lie down quietly when he feels an attack coming on, one or two doses of fifteen grains each of the bromide of lithium will enable him to sleep, and wake free from pain. I have found the lithium bromide far more valuable in migraine than any other of the bromides. An effervescing preparation known as bromo-caffeine is often efficacious in aborting a paroxysm or in palliating it when it has got under way.

Quinine, in my experience, seems to be of little use in preventing or cutting short a paroxysm of migraine, although Ross¹ has found that a dose of ten or fifteen grains may arrest it. Ergot has been found useful, and, as it acts by contracting the arterioles, should be given only in the angio-paralytic form. The fluid extract of ergot may be administered, but ergotin in pill form is more acceptable to the stomach.

Inhalations of nitrate of amyl have been used with advantage. Berger, who was the first to employ this remedy, found that a single inhalation of a few drops relieved the pain at once, and it did not return that day. It is indicated only in the sympathico-tonica type. If it is used, two or three drops of the nitrate in a glass pearl may be crushed in the handkerchief and inhaled. Nitro-glycerin may also be given in this variety of migraine.

Once the attack has begun fully, we can only attempt to mitigate the pain. Firm pressure on the head generally gives relief, and encircling the head firmly with a rubber bandage is often of great comfort. Compression of the carotids gives temporary but decided ease to the pain. Strong counter-irritation in the shape of a mustard plaster to the nape of the neck or a stimulating application, like Granville's lotion, to the vertex, will afford relief. I have found in some cases that placing a hot-water bag, as hot as could be borne, against the back of the head alleviates the pain. In other instances cold affords more relief, and an ice-bag resting upon the forehead is the most efficacious way of applying cold. Hot bottles to the feet are an accessory not to be overlooked.

In the way of medicine we may give the bromide of lithium every hour. The bromide of nickel has been recommended by DaCosta as

¹ *Diseases of the Nervous System*, vol. ii. p. 558.

having peculiar advantages. *Cannabis indica* may be given in doses of a quarter of a grain of the extract every two hours until relief is obtained. Anstie believes strongly in chloral, and says that a single dose of twenty or thirty grains will often induce a sleep from which the patient wakes free from pain. The same writer advises the administration of muriate of ammonium, but it is too nauseous a dose to be given when the stomach is as much disturbed as it usually is in an attack of migraine.

Croton chloral is preferred by some to the chloral hydrate. Ross, for example, gives it in doses of five grains every four hours until relief is obtained.

Galvanism through the head is often of relief, especially at the beginning of an attack; but this means is not often available, for it is not easy to have the suitable apparatus for the constant current at a patient's home when it is needed. Should galvanism be used, one pole should be placed on each mastoid process, and a weak current passed through the head for two or three minutes. The sympathetic may be galvanized by placing one pole over the upper cervical ganglion, just behind and below the angle of the jaw, while the other pole is held in the hand or placed upon the sole of the foot. In hemiplegia spastica the positive pole is put over the ganglion, and in the angio-paralytic type the negative pole is placed in this location.

Should all of the above means fail, we may resort to morphia hypodermically. Jewell¹ favors the administration of morphia and atropia, either by the mouth or hypodermically, from the beginning of an attack until the pain is eased; but I believe that morphia, except as a last resort, is very undesirable in migraine. Although a small dose hypodermically will usually promptly bring relief, there are the unpleasant after-effects of opium felt, and the patient feels more prostrated and with more disordered digestion than had no morphia been used. Besides, the morphia habit is liable to be formed, especially in women, when the drug has once begun to be taken.

It is for this reason that I prefer to use the bromides, and if a patient is seen at the beginning of a paroxysm, given a fifteen-grain dose of bromide of lithium, his feet put in hot mustard-water, and he then goes to bed, he will almost always cut his attack short, and on waking from sleep will feel refreshed and able to take food.

I am strongly convinced of the importance of arresting or shortening the paroxysms of migraine, especially in the young, at the beginning of the disease. By this means the habit of long attacks is prevented, and their prostrating after-effects are avoided. Should we succeed in checking the first few attacks, we may by tonics and regimen improve and fortify the constitution so as to eradicate or modify the neuralgic tendency.

VERTIGO.

By S. WEIR MITCHELL, M. D.

DEFINITION.—The clinical meaning of vertigo has gone, as is common, far beyond what the term implies. We may define vertigo to be a sense of defective equilibrium, with or without actual disturbance of position, and accompanied by varying amounts of subjective feelings of motion of external objects, of the body itself, or of the contents of the cranium.

SYMPTOMATOLOGY.—Vertigo consists of attacks which are single or repeat themselves during a continuous condition lasting for hours or days, and which I have elsewhere described as the status vertiginosus.¹

The mildest form of vertigo is that in which the patient has a sensation of the contents of the head as being in motion. If more severe, there is disturbed equilibrium, an effort is needed to stand erect, or there is, as in most vertigo, a fear of falling. The brain seems to be moving round or upward. This type is found in insanity, in hysteria, and in the vertigo of mental effort observed in extreme cerebral exhaustion.

In a second clinical species of vertigo the patient appears to himself to be in motion, while outside objects maintain for him their places. This may or may not be accompanied with sensory disturbance or an approach to mental confusion. It is really a delirium of movement. The patient feels as if he were rolling or falling or reeling or dropping through space. Meanwhile, however grave the hallucination, he walks and stands without the least sign of defect in balancing power. These cases are very rare, but are sometimes seen as temporary results of hysteria.

Perhaps it is doubtful whether we should really class this symptom-group as vertigo.

The more common or typical expression of vertigo is marked in its fulness by a false sense of the movement of external objects and of the relations in space of the individual to such objects. The pavement rolls or seems to be coming up in front of him; the houses stand at angles; walls, pictures, chairs, and tables reel around him, are still a moment, and again move; or the bed seems to be aslant or to rock to and fro. In extreme instances objects are seen as if inverted, and whenever the vertigo is marked the victim reels or falls, or seeks by rest supine or by closing his eyes to lessen the terrors of the attack. In severe examples no such help avails, and for hours or days the patient may lie clutching at the bed for support or in deadly fear of a new onset of vertigo,

¹ *Med. and Surg. Rep.*, June, 1877.

which in some cases is brought on by the least movement of the head, by taking food, by efforts to think, or by mechanical vibrations.

In most cases there is some mental confusion, or even brief loss of consciousness at the close of the attack, and nearly always more or less nausea or vomiting occurs—symptoms which have frequently misled observers as to the cause of the vertigo, but which have in most cases only the significance gastric disturbance has in migraine. As in that disorder, but more rarely, the emesis may be associated with or replaced by looseness of the bowels, and is very apt to be followed by a flow of pale clear urine.

Fits of vertigo are often as distinct clinically as epileptic attacks. The patient has for a few moments, in an acute form, all of the phenomena of vertigo, and may then recover promptly, or it may chance that he has a vertiginous status and a series of fits, or remains for long periods in a state of chronic disorder of head, with now and then an acute onset.

Physicians do not often witness these fits: I have been so fortunate as to see several. I take this description of one from my notes: A young clergyman, after excessive overwork among the poor, came to consult me for vertigo. As I talked to him an attack came on. I asked him to keep as composed as possible and to tell me what he felt. He said: "It has just begun. The objects in the room are moving from right to left; I can seem to hold them still for a moment, then they go on and move faster. If I shut my eyes it is relief, but only for a time. I feel myself as if I were now going round with them. The chair rocks, and my brain seems moving too." At the same time he became very pale, and slipped from his seat. His pulse was quick and feeble and rapid, and as he lay on the floor unconscious a profuse sweat broke out on his face. In a moment he was again himself, but did not recover so as to walk for a half hour. He then complained of headache, but was able to walk home. This is a fair example of a fit of vertigo, due, as it proved, to at least two of the causes of vertigo, which I shall presently discuss.

A few persons insist that something like a distinct aura precedes the attacks. In other cases the brain symptoms develop gradually, from a faint sense of dizziness up to a tumultuous feeling of confusion with sensory illusions. In a few rare cases there is, as in that above mentioned, an abrupt onset. Something seems to snap in the head, and the vertigo follows; or, most rare of all, we have a sensory discharge felt as light or sound, and followed by the ordinary symptoms.¹

DIAGNOSIS.—Vertigo is of course, as a rule, only a complex symptom of one or more numerous conditions. Acute isolated fits of vertigo are sometimes puzzling, because epilepsy may be preceded by brief vertigo and exist without notable spasms. Time may bring to us a frankly expressive epilepsy to explain former and less distinct fits. But usually it is the attacks of vertigo which are the causes of doubt. A man has sudden giddiness, and falls unconscious for a moment. These attacks persist. How shall we know them as vertigo? how be secure that they be not some form of the lesser epilepsy? As a rule, if they be vertigo there will be nausea or emesis, while the intervals between attacks will offer the usual signs of confusion of head, fear of losing balance, and all the numerous evidences of disturbed and easily excitable states of the

¹ See the author in lectures on *Nerv. Diseases, Disorders of Sleep*, p. 63, 2d ed.

sensorium—conditions rare in the interepileptic periods. The effect of bromides may aid the diagnosis, for, although often of use in vertigo, they have not such power to inhibit the fits as they possess in epilepsy. Persons long liable to any form of vertigo can readily cause attacks, or at least vertiginous feelings, by closing the eyes while standing, by the least rotation, or by putting a prism on one eye, so that among these tests we may frequently find the material for a diagnosis, which will of course, in many instances, be made easy enough by the presence of causes obviously competent to occasion the one or the other disease.

PROGNOSIS.—In true vertigo, if we exclude the organic causes, and especially intracranial neoplasms, there is very little to be feared. Deaths have been seen in Menière's disease, but are most rare. Even in grave examples of labyrinthine vertigo there is a probability that the worst which can occur will be deafness, and that vertigo will gradually cease as the delicate neural tissues become so degenerated as to cease to respond to irritations.

The **DURATION** of other forms of vertigo it is less easy to predict. Ocular vertiges get well soon after the eye trouble is corrected, and the like is true of most vertiges due to peripheral causes. So also the giddiness which is sometimes seen as a very early symptom in locomotor ataxia is transient, and will be apt, like the ocular and bladder troubles which mark the onset, to come and go, and at last to disappear entirely. It is to be remarked that vertigo at the beginning of posterior sclerosis is common, and is not due to ocular motor conditions.

Sometimes in vertigo, as in epilepsy, the removal of a long-existing cause may not bring about at once a cessation of the abnormal symptoms its activity awakened, so that it is well, as to the prognosis of duration, to be somewhat guarded in our statements. Nor is this need lessened by the fact that vertigo may be an almost lifelong infliction, without doing any very serious damage to the working powers of the person so disordered.

ETIOLOGY.—It is generally taken for granted that vertigo has always for its nearest cause some disorder of cerebral circulation; but while either active congestion or anæmia of brain may be present with vertigo, and while extreme states of the one or the other are certainly competent to produce its milder forms, it does not seem at all sure that they are essential to its being. Indeed, there is much reason to believe that vertigo is due in all cases to a disturbance of central nerve-ganglia, and that the attendant basal condition is but one incident in the attack.

In vertigo there are the essential phenomena, as disturbed balance, with a false sense of movement within or without, or of one's self. Then there are the lesser and unessential phenomena, which vary in kind and degree, and these are the moral and mental symptoms—terror, confusion of mind, and sensory illusions; and, last, the nausea and sickness met with here as in migraine, and the flow of clear, thin urine.

All of these symptoms should be accounted for in speaking of the intracranial organs, disorder of which causes vertigo. Ferrier has especially made it clear that equilibration involves afferent impressions, co-ordinative centres, and efferent excitations preservative of balance.

Guiding impressions, which direct the muscles through centres below the cerebrum, so as to aid in preserving our balance, reach these centres

from the skin and the muscles, so that great loss of tactility or of the compound impressions called muscular sensations results in disturbance of equilibrium, but not in true vertigo, which is clinically this and something more.

A second set of impressions, of use in preserving equilibrial status, come through the eye, or rather habitually through the eyes, because the consensual impressions arising out of double vision and the co-ordinate movements of the two fields of sight have, as is well known, much to do in this matter. It is hardly needful to dwell on this point. Certain parts of the ear have, however, the largest share in maintaining our balance, and it seems likely that the semicircular canals—the part most concerned—although lying within the petrous part of the temporal and receiving nerves from the stem which constitutes the nerve of hearing, may have slight relations or none to the sense of audition.¹ When the horizontal canals are cut, the head moves from side to side and the animal turns on his long axis. When the posterior or lower vertical canals suffer, the head sways back and forward, and the tendency is to fall or turn over backward. When the upper erect canals are cut, the head moves back and forward, and the tendency is to turn or fall forward.

In pigeons, injury on one side may get well, but when the canals are cut on both sides there is permanent loss of balance. In some way, then, these little organs appear to be needful to the preservation of equilibrium; and of late some interesting attempts have been made to explain the mechanism of this function. It probably depends on the varying pressure relations of the endo-lymph to the nerve-ends which lie in the membranous canals.

Wm. James of Harvard has shown that total loss of hearing is usually accompanied by lessened susceptibility to vertiginous impressions, so that the stone-deaf are not apt to be seasick or giddy from rotation, owing to their having lost the organ which responds to such impressions. It would seem also that the entirely deaf have peculiar difficulty in certain circumstances, as when diving under water, in recognizing their relations to space.

There is a general tendency to regard the cerebellum as the centre in which all the many impressions concerned in the preservation of equilibrium are generally received and made use of for that purpose. There may be several such centres, and the matter is not as yet clear. Whatever be the regulative ganglion, it seems clear that it must be in close relation to the pneumogastric centres, to account by direct connection or nerve-overflow for the gastric symptoms. But, besides this, vertigo has clinical relation to moral and mental states not easy to explain, and in extreme cases gets the brain into such a state of excitability that mental exertion, emotion, strong light, or loud sounds share with the least disorder of stomach capacity to cause an attack.

Vertigo may be due to many forms of blood-poisoning, as at the onset of fevers, inflammations, the exanthemata—notably in epidemic influenzas. It may arise in malarial poisoning, sometimes as the single symptom, as well as in diabetes, albuminuria, lithæmic conditions, and in all the disorders which induce anæmic states. Common enough as sign of brain

¹ I have seen a single case of vertigo, with slight deafness on both sides, in which the sense of the position of sounds was absolutely lost.

tumor, and especially of growths in or near the cerebellum, as a result of degenerated vessels, it is also not very rare in the beginning of some spinal maladies, especially in posterior sclerosis, and is not always to be then looked upon as of ocular origin.

Alcohol, hemp, opium, belladonna, gelsemium, anæsthetics, and tobacco are all, with many others, drugs capable of causing vertigo.

In hot countries heat is a common, and sometimes an unsuspected, cause of very permanent vertigo.

Lastly, excess in venery, or, in rare cases, every sexual act, profound moral and emotional perturbations, and in some states of the system mental exertion, may occasion it, while in hysteria we may have almost any variety of vertigo well represented. Outside of the brain grave organic diseases of the heart are apt to produce vertigo, especially where the walls of the heart are fatty or feeble from any cause. Suppression of habitual discharges, as of hemorrhoids or menstrual flow, is certainly competent, but I have more doubt as to the accepted capacity of rapidly cured cutaneous disease.

The following are some of the more immediate causes of vertigo: They are disorders of the stomach or of the portal circulation; laryngeal irritation; irritation of the urethra, as passing a bougie, especially when the patient is standing up; affections of nerve-trunks; nerve wounds; sudden freezing of a nerve (Waller and the author); catarrhal congestion of the nasal sinuses; inflammation and congestion of inner ear, many irritations of the outer and middle ear; prolonged use of optically defective eyes; insufficiency of external muscles of the eye.

It will be needful to treat of some of these causes of vertigo in turn.

Gastric Vertigo.—Trousseau certainly misled the profession as to the frequency of this form, but he did little more than represent popular medical views, and we may now feel sure that a good many so-called gastric vertigoes are due to lithæmia or to troubles of ear or eye. There are, I think, three ways in which the gastro-duodenal organs are related to the production of vertigo. Acute gastric vertigo arises in some persons inevitably whenever they eat certain articles, and the limitations are odd enough. Thus, I know a gentleman who cannot eat a mouthful of ice-cream without terrible vertigo, but otherwise his digestion is perfect. I know another in whom oysters are productive of vertigo within ten minutes; and a curious list might be added, including, to my knowledge, milk, eggs, oysters, crabs, etc. In these cases digestion is arrested and intense vertigo ensues, and by and by there is emesis and gradual relief.

In other cases, owing to over-feeding or any of the numerous causes of acute dyspepsia, an individual has a sudden attack of acid stomach, and as this gets to its worst he has alarming vertigo. In these cases the room whirls around or the pavement rocks; the balancing power is disturbed or lost; the sense of movement in the brain itself is sometimes felt; there are slight buzzing or humming sounds in one or both ears; there may be double vision, which comes and goes, while the power to think is lessened and the terror created is quite unendurable. At last come the sweat of nausea, emesis, and relief, with a gradual fading away of all the symptoms.

As a rule, such an attack need cause no uneasiness as to a fatal result, but, unless the case be handled with skill, it is apt to repeat itself with

or without repetitions of the originating cause, until what I have called the status vertiginosus is created, and we have more or less steadily present a slight sense of defective balance, of confusion of mind, of blurred vision, and, more rarely, of slight noises in the ears. After two or three grave attacks, attacks are added for which the patient sees no cause. He lives in a state of constant terror, and the status vertiginosus attains its highest development, and may last for unlimited periods, while the brain becomes endowed with new morbid susceptibilities. To read, to write, to face sudden sunlight, to see moving bodies or passing crowds, cause vertigo. Loud sounds disturb the balance; even music will affect it. Emotions or any decided mental efforts are equally competent to bring on attacks, while fatigue or sudden changes of posture have to be alike avoided.

I have sketched an extreme case, but whatever causes grave vertigo is able to bring on the set of symptoms here described, which are, after all, more apt to be due to aural than gastric states.

Vertigo as a result of chronic dyspepsia in any of its forms is rare, and as a rule is less severe than that which grows out of acute gastric dyspepsia. The sensory symptoms are trifling, and the confusion of head and the lack of balance less notable, while the vertigo, which is more or less constant, seems to be most often met with two to four hours after meal-time, so that it is usually doubtful as to how much is due to reflected impressions from the digestive tracts, and how much to the direct influence of imperfect material in the circulation.

In a third form the gastro-intestinal tract is but indirectly concerned. In a person who is anæmic, or who is nervous and perhaps hysterical without being anæmic, but in whom it is impossible to detect in the stomach or bowels, in the feces or urine, any sign of defective digestion or of malassimilation, we find that during the act of digestion there is at some time, and in a few cases constantly, some transient but not grave vertigo.

This is due simply to the influence exerted on an over-sensitive head of a normal functional activity, which may act directly as any peripheral cause would act, or may be due, in the anæmic, with this to the withdrawing of blood from other parts of the body which occurs in digestion. It is an illustration of what is too often overlooked, the capacity of a healthy functional act to disturb morbidly a sensitive brain.

Aural Vertigo.—Vertigo may be due to a variety of irritative causes acting on the outer, middle, or inner ear. We shall consider them separately.

Vertigo from Causes acting on the External Ear.—In animals I have found that the injection of iced water or a rhigolene jet into the meatus is at once the cause of convulsive movements in the rabbit, and that repetitions of this cause at last a permanently vertiginous state, so that when a rabbit or guinea-pig thus disordered was shut up in darkness for some hours, sudden sunlight caused it to be for a few moments vertiginous. It is remarkable that while in birds many parts of the skin are competent under irritations (Weir Mitchell, Ott, Brown-Séquard) to give rise to vertiginous phenomena, in mammals only the skin of the external auditory meatus appears to be thus responsive. The author was himself the best illustration of this fact. Some years ago, when by mis-

hap water at about 52° F. was thrown into his left ear, he fell instantly on his left side, with slight disturbance of vision, the room seeming to rock in the direction of the fall—that is, to the left. He arose with some difficulty, his head swimming, and with a distinct sense of lack of power in the whole left side, and with, for a half hour at least, an alarming tendency to stagger to the left.

Thus, injections of cool water in some cases (or in others of water at any temperature), and in certain persons very hot water, will cause vertigo. Foreign bodies—hardened wax, aspergillus, ulcers—or any inflammation may occasion it, while it is curious that usually the painful abscesses of the ear do not, especially in children, who are, as a rule, less liable to vertigo than are adults.

The tendency of aurists is, I believe, to explain the phenomena by either direct influence propagated as sound-waves through the auditory apparatus to the labyrinth, or by admitting inhibitory impressions affecting the vaso-motor loops and causing increased pressure in the semicircular canals. I am disposed to think that the effect may be a more direct one, and to regard the centres as directly influenced through the fifth nerve, including vaso-motor phenomena of course—a question to be, however, easily solved in the laboratory.

In this form of vertigo tinnitus is slight or transient, coming and going, or if permanent but faintly felt.

Middle-ear vertigo may arise from any inflammation of the part or from closure of the Eustachian canal. There are then direct mechanical influences affecting the labyrinth, as well as sensory irritations, not causing auditory phenomena; whilst also the inner ear is apt soon to suffer from direct propagation of inflammatory processes. There is then paroxysmal vertigo, variable hearing,¹ and early tinnitus.

Inner-ear vertigo seems to be due to irritations, auditory, mechanical, or inflammatory—whatever disturbs seriously the nerves of the semicircular canals, since, if we may trust recent research,² the cochlea is not a source of vertiginous impressions. This form of vertigo was first described with pathological proof by Menière in 1860, and is probably in its variety of degrees the most common of all the origins of dizziness.

The acute attack is nearly always preceded by more or less deafness, and in many cases by middle-ear catarrh,³ with or without tinnitus. More rarely all the symptoms arise abruptly. There are sudden tinnitus, deafness, nausea, vertigo. The loss of hearing remains, and is variable, or, finally, the hearing is lost altogether. The tinnitus is permanent or varies in amount, but as the deafness grows complete the vertigo disappears, and although cases of death have been described, labyrinthine vertigo is, as a rule, prone to get well in time.

Single attacks are rare. It is apt to repeat itself, and finally to cause all the distressing cerebral symptoms which characterize the worst gastric vertigo, and at last to be capable of easy reproduction by light, heat, over-exertion, and use of the mind or eyes, by emotion, or by gastric disorder.

Even after the vertigo has ceased to exist the fear of loss of balance remains, while perhaps for years the sense of confusion during mental effort continues, and gives to the sufferer a feeling of what a patient

¹ Burnett, *Sect. Otol., Int. Med. Cong. Proc.*, 1876.

² Gellé.

³ Burnett.

described to me as mental vertigo—some feeling of confusion, lack of power to concentrate attention, loss of hold on trains of thought, with now and then a sensation as if the contents of the cranium moved up or down or swayed to and fro.

The attack in the gravest forms is often abrupt, and, according to Charcot, is always preceded by a sudden loud noise in the affected ear. I have, however, notes of many cases in which this was not present. The patient reels, staggers, or falls, usually forward or to one side, loss of consciousness being very rare. The sensory hallucinations are remarkable. If at rest or after his fall he seems to himself to sway, and tends to pitch or roll over; the bed rocks, the room and its contents reel. The patient's terror is intense; he clutches the bed; seeks relief in fixing his eyes on an object, which in slight attacks is competent to relieve, or else he closes them. The least motion starts the vertigo afresh. In some cases turning the head or looking up will bring it back, or the patient may remain for days or weeks in this condition, with continuous dizziness and frequent recurrences of severe vertigo, while there is more or less constant nausea and sometimes vomiting.

There should be no trouble in distinguishing the cases in which deafness exists, but the nausea is apt to direct attention to the stomach. Tinnitus is common in vertigo, however arising; and when, as I am sure does chance, there is for years now and then a slight and transient deafness with vertigo, or a permanent deafness in one ear, and therefore not noticed, the inner ear is apt to be overlooked as a source of trouble.

Vertigo from growths on the auditory nerve before it enters the inner ear is rare in my experience. It is described as slow in its progress, the deafness and tinnitus being at first slight, but increasing steadily, while there is tendency to fall toward the side affected.¹ In the cases of disease attacking the seventh nerve within the cranium there is usually so much involvement of other and important nerve-tissues as makes the disorder of audition and equilibration comparatively unimportant.

Vertigo from coarse organic lesion of brain, such as a tumor, is common, and is, indeed, rarely absent in such cases. The cases in which it is lacking or least remarkable are, I think, to be found in the anterior and middle cerebral lobes, while it is almost sure to exist at some time when the tumor is in or near the cerebellum.

Growths or other causes of irritation in the crura of the cerebrum or cerebellum, or on the pons, are sure to give rise to disturbed equipoise or to methodical involuntary actions; but these are not always, though often, accompanied with delusive impressions as to exterior objects, or with the other symptoms found in typical vertigo. I recall one remarkable case where a blow on the left side of the occiput resulted in a tendency to roll to the left which finally triumphed over volitional control, so that the patient would at times roll over on the floor until arrested by a wall. After the rotation had lasted for a minute there was, when it ceased, a false sense of movement of objects to the left, but at the outset there were no sensory illusions, and at no time any mental disorder. The patient recovered, and is now in good health; but it is interesting to learn that while, during the time of these attacks, he had normal hearing, he has gradually lost hearing in the left ear and acquired permanent

¹ Burnett.

tinnitus. I have reached the conclusion that there is a group of functional vertigoes, and that in some of them the trouble lies in the semi-circular canals; that is to say, the lesion is slight or transient, but in rare cases recurs until a more distinct and permanent result justifies the original diagnosis.

OCULAR CAUSES OF VERTIGO.—For the most part, the eyes as a source of vertiginous impressions are neglected in the textbooks; but as the cause of certain of the slighter vertigoes, and as a fertile agent in emphasizing or recalling vertigoes due to the stomach or inner ear, they are well worthy of careful study, nor is it ever wise to neglect these organs in cases either of headache or of vertigo.

A number of eye conditions cause giddiness or increase it or reproduce it. Thus, sudden loss of accommodation in one eye or in both may occasion it, and perhaps the enlarged pupil may have its share, since even in healthy people, and surely in all habitually vertiginous patients, sudden exposure to brilliant light gives rise to sense of instability.

Abrupt change in intraocular pressure is another cause, as in acute glaucoma or in sudden partial collapse of the eye from discharge of the aqueous humor.

Permanent vertigo of quite severe character may arise from astigmatic defects, and from almost any form of disorder affecting steadily the power of the eye to accommodate itself to distances; but simple myopia of moderate grades, excessive one-sided myopia, or presbyopia is unlikely to do so. Oculo-motor troubles, paralytic or spastic, are very effective causes of vertigo, which is sometimes quite promptly producible by the wearing of a prism on one eye or by the use of glasses which over-correct, or if exact are for some reason badly borne. This latter is apt to be the case, I think, in accurate corrections of long-standing hypermetropic astigmatisms. There is one point on which, in this connection, I have again and again insisted: Optically defective eyes may exist through life without notable brain disturbance, unless, from over-use with worry, work under pressure, the strain of prolonged or of brief and intense emotion, or any cause of ill-health, the centres become sensitive, as they are then apt to do. When this occurs defective eyes, and in fact many other sources of irritation, grow at once into competence for mischief, and occasion vertigo or headache or other cerebral disorders.

Then it is that even slight defects of the eye may cause vertigo, which if usually slight and transient, coming and going as the eyes are used or rested, is sometimes severe and incapacitating. I have over and over seen vertigo with or without occipital pain or distress in persons whose eyes were supposed to be sufficiently corrected with glasses, but who found instant relief when a more exact correction was made; and this is, I think, a matter which has not yet generally received from oculists the attention it demands.

When vertigo, essential, gastric, or aural, is present, the use of the normal eye becomes a common source of trouble. Bright lights, things in irregular motion, reading or writing, and especially rapid changes in accommodation, as watching the retreat or approach of a moving object, are prone to cause or increase the dizziness.

Vertigo in old age, if not due to the stomach or defective states of the portal system, kidneys, or heart, is either caused by atheromatous vessels

or multiple minute aneurismal dilatations of vessels, or in full-blooded people by some excess of blood or some quality of blood which is readily changed by an alteration in the diet, of which I shall presently speak. Whatever be its source, it is in the old a matter of reasonable anxiety.

Laryngeal Vertigo.—Under this name J. R. Gasquet,¹ and later M. Charcot, have described a form of vertiginous attack in which irritation of the larynx and a spasmodic cough invariably precede the onset. I have never seen such cases, nor do they seem to me entitled to be called vertigo. The symptoms are these: After bronchitis, gout, or rheumatism there occurs an irritation of the larynx or trachea, or of both, which at times is expressed in the form of a tickling cough, simple or in spasms. With these arises a slight sense of vertigo, or else in the grave attacks the patient falls insensible, without convulsion or with no more than one may see at times in fainting. The face is flushed, even deeply, and the attacks last but a few moments. The term vertigo seems to have in such a group of symptoms but little application, nor do these attacks ever bring upon the sufferer the status vertiginosus.

Vertigo in Anæmia and in Neurasthenia and Hysteria.—A passing vertigo readily caused by abrupt changes of posture, felt even in health, at times is far more profoundly experienced in grave anæmic states, while in neurasthenic conditions, with deficiency of globules or defect of hæmoglobin, it is still more common. In well-pronounced neurasthenic states, where there is no measurable lack of red corpuscles, but where hæmoglobin is apt to be deficient, it is a frequent symptom, and is then either an immediate result of functional central disorder or of gastric or optical troubles. While the dizziness of neurasthenia is never profound, certainly never repeats the agony of Menière's vertigo, it is apt to be but a too constant symptom, and to be, like the other disqualifying cerebral symptoms of neurasthenia, almost the last to get well. Usually there is little, often no, tinnitus, no deafness, no nausea, slight but a pretty constant sense of unsteadiness, and rarely or but for a few moments any false subjective visual illusions. This, at least, is the type, but, on the other hand, in extreme cases and within these limits the brain is liable to be confused, and the sense of need for difficult controlling volitions called out by almost any use of the eyes in near vision, owing usually to oculomuscular paresis. Even looking at a mirror or at persons passing by, or the least distinct mental effort, may reproduce it. There is, too, in most of these cases an extreme sense of mental confusion, and more often a false sense of movement within the head than without, while in no other patients is the sexual act so apt to increase all of the symptoms in question.

Hysteria, as might be expected, offers now and then examples of vertigo. It does not exclude the presence of true aural, optic, or gastric dizziness, which is then apt to become the starting-point of a long train of hysterical disorders. On the other hand, we meet with hysterical vertiges which, in a sense, may be said to simulate any of the more usual types. I have certainly seen hysterical girls with deafness, tinnitus, and a great development of equilibrial disturbance, in whom the disease passed away without leaving a trace behind it, so that in these cases some caution is needed as to prognosis. They become far more difficult to deal

¹ *Practitioner*, Aug., 1878.

with when they are found in old women or women in advanced middle life, since it is then hard to know what share senile changes may have in the production of the symptoms.

Vertigo from mechanical causes, such as sea-sickness, railway sickness, swinging, etc., it is hardly worth while to deal with here at length. The research of Prof. James has made it probable that disturbances of the labyrinth are responsible for the vertigo of sea-sickness. Certainly, deaf-mutes seem to have lost the power to be made vertiginous from rotation, and do not suffer at sea.

It is, however, worth recording here that I have more than once seen enduring vertiginous status, with occasional grave fits of vertigo, arise out of very prolonged sea-sickness. In the last example of this sequence seen by me there was, after a year or more, some deafness.

The elevators in use in our hotels sometimes cause, in those who live in them all day and control their movements, a cumulative vertigo, and I have known such persons to be forced on this account to seek other occupation.

Essential Vertigo.¹—There can, I think, be no doubt that the centres may evolve the symptom vertigo from causes which are transient, and the nature of which sometimes evades our most careful search. We reach the diagnosis of a state of essential or true central vertigo by exclusion, but, once developed, this vertigo does not greatly differ from vertigo of peripheral cause. It is sometimes associated with states of pallor, at others with flushing, while the disturbance of balance and the false perceptions as to the place of outside objects may vary from the least to the most profound disturbance. In some of these examples the nausea or emesis does not appear at all, and the patient, escaping acute attacks altogether, may with occasional aggravation continue to be merely and almost constantly vertiginous.

The TREATMENT of acute attacks of vertigo, however caused, consists, of course, in rest in bed and in the use of large doses of bromides or hydrobromic acid, and if the trouble be grave in that of hypodermatic injection of morphia, and where there is plainly pallor of face in inhalations of amyl nitrite or in the exhibition internally of nitro-glycerin and alcoholic stimulants. Sometimes to lie on the floor in total darkness is helpful when the disorder continues and is severe. I have known patients liable to be attacked suddenly to carry a little flask of brandy, and to find that very often an ounce of brandy, taken at the first sign of trouble, would enable them, by also lying down, to break the attack; and ether is yet more efficient. After the severer sense of vertigo has gone they find that stimulus is comforting, and for a time at least gives strength. I have used amyl nitrite but twice. In each case it is said to have broken the attack, but I have had no larger experience with it.

Gastric vertigo demands, in the acute attacks, a treatment directed to the cause. Antacids may be valuable, or in arrested digestion emetics, but in all cases these should be followed for some weeks by moderate doses of bromides, while gouty or lithæmic states should be treated by the usual means.

Vertigoes from portal disturbances are best treated by aperients, and a like lessening of animal food, which, in the vertigo of old age or middle

¹ Ramskill and others.

life arising from excess of blood, will also be found available. The change of cerebral states of passive congestion, which can be brought about by a pure vegetable or milk-and-vegetable diet is sometimes quite remarkable; and I know of few things in therapeutics which are more satisfactory.

The treatment of anæmic or neurasthenic vertigo involves nothing peculiar. So long as the want of blood lasts, or some one of the several groups of symptoms loosely classed as neurasthenia exists, so long will the associated vertigo endure.

Aural vertigoes are easy or difficult to treat, as they arise from external or middle and internal ear troubles. Irritations in the external ear are of course to be removed, and catarrh of the middle ear to be treated by attention to its conditions, whether of blocking of the Eustachian canals with depression of the membrana tympani or of accumulations in the middle ear, with the opposite state of fulness. Aural vertigo, as has been pointed out, may arise from disorders of any part of the ear, so that it is needful to look for wax, ulcers, foreign bodies, etc. in the external meatus; for catarrhal states, closure of the tubes of Eustachius, states of fulness or of vacuum in the middle ear; and for inflammatory conditions, direct or transmitted, in the inner ear. Very often vertigoes from irritations of the outer or middle ear may be relieved with more or less ease, but labyrinthine vertigo, however acquired, is always troublesome, often lasting, and if grave gets well only when deafness has become great.

In this form of vertigo, and while acute, morphia is very serviceable, and is to be used with full doses of bromides. When, as happens, both cease to be of value, Charcot's plan of the heroic use of quinia salts I have seen do good; but it is advisable to use with it hydrobromic acid in full doses. It has been constantly my practice to employ over the mastoid or on the neck frequent but not deep cauterization. It is well in these cases to warn some near relative that while remote relief from the vertigo is probable, it will be bought at the cost of increasing deafness, and that we can rarely do more than help the patient to endure his state until time and the slow processes of pathological change have come to our aid.

Optic vertigo, if essentially that, is rarely discovered without the help of some one trained to study the defects of vision. Its relief demands, of course, as a rule, glasses, or in extra-optical muscle-troubles these or a compensatory operation. When, however, the vertigo has been grave, it is needful to manage corrections of the eyes with care and judgment, and sometimes experimentally. The sensorium, having become over-excitabile, does not always bear accurate correction of the eyes, or this increases the vertigo. Then the glasses are cast aside and the case progresses. In others—and this is purely a matter of individual experimentation—nothing will answer except the most careful and absolute corrections: anything less does no good.

These remarks apply with equal force in chronic vertigoes, essential, gastric, or other. Defective eyes, unfelt in health, soon begin to trouble a head sensitized by chronic dizziness, and optical defects which are sometimes but trifling become then competent to increase the growing intracranial disorders, or to assist lithæmia or a troublesome stomach to create and sustain vertigo.

The Status Vertiginosus.—I have tried to make clear elsewhere and in this article that in several forms of vertigo the disorder ceases to owe its onsets to extracerebral irritations, and becomes essential, precisely as happens in some epilepsies, and that we then are apt to have, with more or less distinct attacks or with no attacks, long continuance of a group of symptoms which constitute the status vertiginosus. Its treatment is important, because of its alarming and disqualifying effects. The attacks are often the least part of it, while the lack of power to read and write, to go into crowded streets, to face light, or to exercise, or stand emotions or the slightest mental strain, surround its management with embarrassments, and are well fitted to end in melancholia or hypochondriasis.

In these cases, after the eye has been corrected, the diet should be regulated with care. In extreme cases it may become desirable to limit it to milk, fruit, and vegetables where no obvious peculiarities forbid such a regimen; and I have found it useful to insist also on some food being used between meals.

I like, also, that these patients rest an hour supine after each meal, and spend much time out of doors, disregarding their tendency to lie down. Exercise ought to be taken systematically, and if the vertigo still forbids it, massage is a good substitute. At first near use of the eyes is to be avoided, and when the patient resumes their use he should do this also by system, adding a minute each day until attainment of the limit of easy use enjoins a pause at that amount of reading for a time.

Now, as in vertigo, especially labyrinthine, the eyes become doubly valuable as guiding helps to correct equilibration, I have long found it useful to train these patients to stand and walk with them closed. At first this is as difficult, or may be as difficult, as in locomotor ataxia, but the practice is sure to add steadiness to the postures. Somewhat later I ask my patient deliberately to make such movements of the head and such efforts of mind or memory as are apt to cause vertigo or confusion of head, and to conquer or inhibit these consequences by a prearranged effort of will; and these means also I have found useful. Meanwhile, nothing usually in these cases forbids the use of tonics or of moderate doses of bromides. As I have said, change of air is very serviceable. It is indeed rare that cases do not yield to some such combination of means, but very often it will happen that the fears of the patient are his most grievous foes, and are to be dealt with after every real symptom has vanished.

TREMOR.

By WHARTON SINKLER, M. D.

TREMOR is a prominent symptom of many diseases of the nervous system, and is met with as an effect of certain poisons which have been taken into the system; so it should not be considered as a disease in itself. It may, however, occur without being associated with any other abnormal condition which can be discovered. It is then called tremor simplex or tremor essentialis. The tremor of old age (tremor senilis) comes under this head.

Tremor is sometimes hereditary, and may exist from early life. I have a patient in whom there is a trembling of the hands which has lasted since childhood. This lady's mother and grandmother both had the same form of tremor, and one of her own daughters also has it. In this case the trembling is most marked when voluntary movements are attempted, but it does not materially interfere with writing, sewing, or any other act she wishes to accomplish. There is slight tremor when the hands are at rest.

Tremor simplex is seen in hysteria. In this disease it affects the hands and the facial muscles as well. It is not uncommon in these cases to find the tongue tremble excessively when protruded.

Tremor from chronic poisoning is usually from the absorption of lead, mercury, or some of the narcotic drugs or alcohol. Lead tremor is to be looked for among persons who are exposed to the action of lead, such as painters, printers, or manufacturers of white lead.¹ Such persons generally have had some other symptom of lead-poisoning, such as colic or paralysis. The tremor, however, may be the only symptom of saturnine poisoning. Mercurial tremor is not so often seen. It occurs in looking-glass makers or those who work in quicksilver, and may also be a result of the medicinal administration of mercury. The tremor from the excessive use of alcohol or opium is familiar to all. Tobacco, if used immoderately, also causes trembling in the hands. Tea or coffee may have the same effect. There are other drugs which, when taken for a length of time, are liable to cause tremor. Quinine is one of these.

Exhausting diseases, like the fevers, or any conditions which enfeeble the system, cause tremor which occurs in voluntary effect. I saw a lady some years ago who was greatly weakened by a malignant growth. She was extremely anxious to sign her name to a legal paper, but, although the hand was perfectly quiet when at rest, when she attempted to write

¹Lead in hair dyes or in cosmetic powders often gives rise to plumbism by its absorption by the skin.

the first letter such intense tremor came on that it was impossible for her to make any mark which was legible.

Tremor follows violent bodily exertion or mental excitement. The action of cold or the chill of intermittent fever is accompanied with an extreme degree of trembling, which we all know. Tremor is also a result of neuritis, but in this case it is associated with other symptoms.

SYMPTOMS.—Tremor is met with as a fine or a coarse trembling. We may also find a fibrillar tremor, such as exists in progressive muscular atrophy. Tremor is divided by some (Van Swieten, Charcot, and others) into two classes: the first is where the tremor occurs while the part is at rest; the second is where it comes on during volitional muscular movements. The former has been termed by Van Swieten tremor coactus, because he believed that it arose from an irritation which affected the nervous centres in an intermittent way. The latter he conceived to depend upon a defect of stimulus, the result of an insufficient amount of nervous fluid, which causes contraction of the muscles under the influence of the will. This he called tremor a debilitate.¹

In paralysis agitans we have an example of tremor coactus, and in disseminated sclerosis, where the tremor occurs only as muscular effect, it belongs to the variety of tremor a debilitate. Those divisions, however, are of but little importance.

When tremor first begins it is slight in degree and extent, and occurs generally only on voluntary effort. Later there may be a constant trembling even when the part is at rest. Beginning usually in the hands, it may extend to the head and legs. It is seen in the tongue and facial muscles after the disease has lasted for some time.

In some cases the trembling can be controlled to some extent by a strong effort of will. The tremor from alcohol or opium is most marked when the individual has been without the use of the stimulant for a short time, and the trembling may be temporarily checked by renewing the dose of alcohol or opium as the case may be.

The muscular trembling from plumbism and mercurial poisoning is more violent than the other forms of simple tremor, and often resembles the tremor of paralysis agitans. In toxic tremors there are often secondary parietic symptoms and indications of other disturbances of the brain and nervous system.

In simple tremor there is no loss of muscular power, and the electrical reactions of the affected muscles are not abnormal. The duration of simple tremor is almost always great. Usually it persists throughout life, becoming more general and more intense as the subject of it grows older. The tremor of hysteria is shorter in duration. Occasionally there are seen cases of simple tremor, which are apparently the result of some trivial cause in a nervous person, which last but a short time.

I have seen a case of tremor of the head in a woman of about forty years, in which the trembling ceased entirely after it had lasted several weeks. Hammond² describes what he calls convulsive tremor. Under this name he includes cases of non-rhythmical tremor or clonic convulsions, which are unaccompanied by loss of consciousness, but are paroxysmal in character. Pritchard in 1822 presented an account of this affection and

¹ Charcot, *Lectures on Diseases of the Nervous System*.

² *Diseases of the Nervous System*, p. 696.

Mercurial tremor
differs from tremor of
paralysis agitans
in that the tremors
are increased by
voluntary movements,
wh. they are inhibited
or tremor a debilitate
not tremor coactus.

related two cases; Hammond mentions six cases. The affection is characterized by paroxysms of violent and rapid convulsive movements, which are more or less general and occur many times a day. The seizures last from a few minutes to several hours.

The PROGNOSIS in convulsive tremor seems to be favorable.

Tremor may be regarded as a form of clonic spasm. It consists of slight intermittent contractions of individual muscles or groups of muscles. Fibrillar tremor, such as is seen in progressive muscular atrophy, depends on contractions and relaxations of the muscular fibrillæ, and can be seen under the skin, but does not cause any movements of the limb.

There are no pathological data for explaining what portions of the nervous system are the seat of disease in simple tremor. In experiments upon the lower animals it has been found that trembling occurs in muscles which have been separated from the nerve-centres by division of the nerve. So too in man: when there has been a wound or section of a nerve accidentally, there is likely to be tremor in the muscles which it supplies.

The tremor does not begin at once on section of the nerve, but comes on after a few days. As the peripheral end of the nerve undergoes degeneration the tremor increases. It may last months or even years.

In some of the conditions where tremor occurs the influence of the will is weakened or is entirely absent. This is seen in hysterical trembling and in the tremor of old age as well as in those cases where there is general enfeeblement of the body, as in the fevers.

Trembling is connected with disease of the pyramidal tracts, because in this way the influence of the cerebral centres is withheld from the muscles. When a muscle is in a condition of tonic spasm, it is the result of the running together of very rapidly-repeated muscular contractions. It is like the contraction in a muscle from an interrupted electrical current. If the interruptions are slow, the muscular contractions are seen at intervals like a tremor; but if the interruptions are rapid from frequent vibrations of the hammer of the instrument, then the contractions in the muscle are fused together, as it were, and the muscle is in a state of tonic spasm.

It is held by some writers that tremor is caused by the want of balance between the cerebrum and cerebellum. When, for example, the control of the cerebrum is enfeebled the action of the cerebellum is so great as to bring about tremor by its uncontrolled power.

If we accept the first view, we must consider the tremor as a preliminary stage of paralysis; for the lesion, which at first is slight and causes only an interruption of the conduction of impulses from the brain to the muscles, as it becomes more extensive totally prevents conduction, and paralysis ensues.

Hughlings-Jackson's view, that general convulsions are the result of discharges from the cortex of the brain, and that the tonic contractions of tetanus are caused by discharges from the cortex of the cerebellum, may be applied to the pathology of tremor as well. When, for instance, in a disease like disseminated sclerosis a voluntary effort instead of causing a steady muscular contraction results in irregular spasmodic contractions and relaxations of the muscle, we may imagine that a series of discharges were taking place from the cortex of the cerebellum as long as the voluntary efforts were persisted in. On the other hand, in paralysis agitans

it is more probable that a lack of conducting power in the pyramidal tracts prevents the influence of the centres being continuously exerted upon the muscles through their motor nerves.

It is probable that in simple tremor the lesion is situated in the spinal cord; for in this disease we seldom see any evidences of cerebral disturbance. There are no paralytic or psychical symptoms, and no vertigo. In toxic tremors the disease is no doubt located in the brain, for accompanying the trembling resulting from alcohol, opium, mercury, and other drugs are mental changes and more or less muscular enfeeblement.

TREATMENT.—Should the tremor depend upon some cause which can be discovered, of course the obvious course is to attempt to remove the source of trouble. The effort is of greater or less success in different conditions. The tremor from mercurial poisoning sometimes yields to treatment which is directed to the elimination of the mercury. The free administration of the iodide of potassium is the best means to be used, and is often successful. The same means are available in lead tremor. Of course the patient must be removed during treatment from the risk of further absorption of the poisonous substances.

In simple tremor many remedies have been recommended, but the results of treatment are not encouraging. Baths of various kinds and galvanism have been used, and many drugs are advised. Hyoscyamus and its alkaloid, hyoscyamine, have enjoyed a high reputation, and good results have been reported from their use. I have seen relief, but not cure, from their administration. Arsenic is a more reliable remedy and it may be used hypodermically. Eulenburg¹ has used this method with good results. I have given arsenic per orem with beneficial effects in cases of simple tremor. In a case to which I have referred above the tremor was relieved while the patient was taking Fowler's solution, and on changing to hyoscyamus the trembling got worse. On returning to the arsenic the symptoms improved, and finally the tremor ceased after the remedy had been taken for some weeks. Hysterical tremor requires that the hysteria should be relieved. Franklinic electricity sometimes controls the tremor in these cases.

PARALYSIS AGITANS.

By WHARTON SINKLER, M. D.

SYNONYMS.—Parkinson's disease; Shaking palsy; Trembling palsy; Senile chorea; Chorea festinans. The first name is due to the fact that the disease was first fully described by Parkinson in a book published in England in 1817.

Paralysis agitans is a neurosis, chronic in its forms and characterized by a tremor which gradually increases in extent and severity. The tremor is not increased by voluntary muscular movements. A peculiar manner of walking, known as festination, comes on later in the disease, and there are also alterations in the attitude of the head and trunk.

It is a disease which belongs to middle age, being rarely seen before forty years, although cases are quoted by Charcot as early as twelve and sixteen years. Constant and prolonged exposure to dampness and cold seems to bring on the disease, and it is sometimes caused by sudden emotion, like fear or distress. The following case is an instance of the latter:

Case I.—Mr. A. M——, æt. fifty-two years, consulted me Oct. 1, 1883. He is a bookbinder by occupation. His habits have been good. He had a chancre in 1861, but had no secondary troubles. He was in the army from 1861 until 1866. In 1866 he went into business for himself, and, although his business was large, he had no great anxiety or worry. His general health has been good, and he has had no illness except an attack of malarial fever about six years ago. In May, 1883, he was standing by an elevator door on the fourth floor of his place of business, and, seeing that the elevator was caught by something, released it. It immediately fell with a crash to the second floor, and as there were two or three persons on it, Mr. M—— thought they must have been killed or severely injured. He was greatly excited and alarmed, and soon after he had assured himself that none of the occupants of the elevator had been hurt, discovered a trembling of the right hand. The tremor has continued ever since, and has extended to the arm and leg.

On examination there is seen a coarse tremor of the right arm and leg while the limbs are at rest. A voluntary muscular movement stops the tremor, and it also ceases during sleep. When he makes an effort with the right hand, as, for instance, in squeezing the dynamometer, the tremor ceases in the arm, but becomes greatly exaggerated in the right leg. While occupied in doing anything he does not notice the tremor, and it stops when he is lying down.

The dynamometer shows, right hand 150°, left hand 120°. After two years have elapsed the disease has gradually progressed in severity.

SYMPTOMS.—The course of the disease has been divided into three stages—the period of invasion, the stationary period, and the terminal period.¹

Period of Invasion.—There are several modes of invasion, but the most frequent by far is slow in its onset. The disease comes on gradually, first showing itself as a slight tremor in the hand or fingers while the part is at rest. It is not constant, and ceases as soon as the patient's attention is called to it. There is sometimes preceding the tremor rheumatic or muscular pain in the affected arm. The tremor may first occur in the foot. Should the disease begin in the hand—and this is most common—the movements are peculiar. They may consist of a fine rhythmical tremor, or the fingers move in a methodical way over each other. Charcot speaks of the thumb and forefinger being rubbed together as if the patient were spinning wool. While this movement of the thumb and finger is going on the wrist is being flexed by jerks. During the early stages of the disease the tremor is observed only at intervals. It comes on intermittently when the patient is not thinking of it and while the limb is at rest, and ceases as soon as any voluntary muscular effort is attempted. The act of grasping the hand or taking up an object is enough to check it for the time. In a patient now under my care I have often noticed during the early stages a well-marked tremor of the right hand while it was lying in her lap, but it would at once cease when I called attention to it. As soon as the mind of the patient was diverted to some other subject the tremor would begin again.

As the disease progresses voluntary effort no longer controls the tremor, or if it does at all it is only for a few seconds, when it begins again. As the tremor increases in violence it extends to other parts of the body. At first it may have been confined to the hand; now it extends to the arm, a little later to the foot and leg on the same side. Then the other arm will be affected, and finally all of the limbs will succumb to the tremor.

Charcot speaks of decussated invasion—that is, the disease begins in the right upper extremity, for example, and next passes to the left lower extremity. This is a rare form; it is much more frequent to see the hemiplegic type, which may persist for some time, or the paraplegic type, when both legs are affected.

There is a progressive form of invasion when the tremor is not the first symptom. The patient has neuralgic or rheumatic pains in the limbs, which are afterward affected with tremor. Sometimes there is some mechanical injury of the limb, which subsequently is the seat of pain and tremor. The general health of the patient is at the same time more or less impaired. There is a sense of general weakness and lassitude; the temper is irritable, and there may be some vertigo. The features and countenance are characteristic even at the earliest periods of the disease. There is an absolute absence of expression, and the features are fixed. The face looks like a mask, and although the patient may smile or laugh, immediately after the features return to the original blank expression. Amidon showed two cases of paralysis agitans to the American Neurological Society in 1883, in which there was no tremor whatever, but all the other features of the disease were present.

¹ *Lectures on Diseases of the Nervous System*, by J. M. Charcot.

After a great mental or moral shock the trembling begins suddenly, abrupt invasion, as in Case I., or the case described by Charcot, where the wife of a gendarme, seeing her husband's horse return riderless to the barracks, received a shock of great severity, which was followed on the same day by tremor. The tremor is at first confined to one limb. It may even disappear for a time, but gradually and slowly extends to the other limbs, and takes the same progressive course.

Period of Stationary Intensity.—After the disease has become fully developed the tremor is incessant. The intensity is not the same all the time. It may be augmented by cold, over-excitement, or voluntary effort, and is lessened by repose and sleep. The trembling ceases during anæsthesia.

During this time all the characteristic movements are at their height. The moving of the thumb and finger, already referred to, is present, and seems like a partly co-ordinated movement. Charcot describes these movements as being in some cases like the rolling of a pencil or a paper ball between the thumb and finger, and in others the movements, he says, are more complicated, and are like what occur in crumbling a piece of bread.

The handwriting is almost illegible, and every letter shows the excessive trembling of the hand, most marked in the up strokes of the pen. All this time the head and neck are unaffected. There is no nodding or shaking of the head to be observed on the closest inspection. This is an important fact to bear in mind, for it is a distinguishing feature between the disease under consideration and disseminated sclerosis. There is no nystagmus, and the muscles of the jaw are unaffected by tremor. The tongue, however, while lying on the floor of the mouth undergoes tremor, and this is increased when the organ is protruded.

The speech is slow and jerky, and the patient usually speaks in a low tone of voice. He eats his food without difficulty, but in advanced cases the saliva sometimes escapes from the mouth during deglutition. A characteristic symptom of the disease is a rigidity of the muscles of the extremities, trunk, and of the neck. When the muscular stiffness first begins the patient complains of cramps followed by a sense of rigidity. The flexor muscles are first affected. This stiffness causes peculiarities in the patient's attitudes. The head and neck are usually bent forward, and seem fixed in that position. The body is inclined slightly forward in standing. The elbows are held somewhat away from the chest, the forearms are flexed on the arms, and the hands are flexed on the forearms. The thumb and forefinger are extended and brought together as if holding a pencil. The other fingers are also flexed. The attitude of the hand and the prominence of the knuckles make it closely resemble the hand of rheumatoid arthritis. In paralysis agitans, however, there are no bony deposits in the joints, and no cracking is heard on bending the knuckles.

In the lower extremities there is often intense rigidity. Contractions occur, and the legs are strongly flexed. The feet often are extended in the position of equinus. It is this rigidity which causes the difficulty in walking (Charcot).

The gait of the patient now becomes very striking. He gets up from his seat slowly and with difficulty ; hesitates a moment before starting to

walk; then, once having made a few steps, goes at a rapid pace. The tendency is to fall forward; in order to preserve his equilibrium the patient hurries forward as if to catch up with his centre of gravity. This gait has been called *paralysis festinans*—*festination* or *propulsion*.

Although propulsion is the usual form the gait assumes, sometimes there is a tendency to fall or run backward. This tendency is not always apparent even when it exists. Charcot has a method of showing its existence which is very successful: when a patient is standing he pulls her slightly backward by the skirt, and this is sufficient to start a movement of *retropulsion*.

Propulsion and retropulsion are not necessarily always present. Many cases progress to the end without these symptoms.

As the disease advances the muscles become more rigid and the patient is confined to bed. He is, however, restless from a sense of prostration and fatigue. He is unable to turn himself, and often calls to his attendant to change his position. The sufferers from this disease, although not having actual pain, complain of disagreeable sensations. There is a constant sense of excessive heat whether the temperature of the room be high or low. In winter they cannot bear much bed-clothes at night, and prefer to wear very light clothing. Associated with this sensation of heat is often profuse perspiration (Charcot). Notwithstanding all these troublesome sensations the sensibility of the skin is not changed. Heat and cold are readily felt, and there is no *anæsthesia* or *analgesia*.

Terminal Period.—The duration of *paralysis agitans* is generally great. The disease may extend over many years—even as long as thirty years in some cases. As the tremors and rigidity increase in intensity the patient becomes obliged to sit all day in a chair or is confined to bed. Occasionally the tremor becomes less while the rigidity increases. The nutrition suffers, and the muscles especially become greatly wasted. Up to a certain point the intellect remains unaffected, but late in the disease the mind fails. General prostration of the whole system sets in, bed-sores occur, the urine and feces are passed unconsciously, and the patient dies of exhaustion. It is not often that the end comes in this way. It is much more frequent that some intercurrent disease, like pneumonia, ends the life of the patient. The disease is undoubtedly a most painful and trying one to both patient and physician. It lasts for years, and there is no prospect of relief. Charcot says that he has seen the terminal period last for three or four years. The following case is a fair example of the disease:

Case II.—Margaret Hays, aged fifty-four, single, applied for treatment at the Infirmary for Nervous Diseases, Oct. 9, 1882. She is housekeeper for her brother, who keeps a restaurant. She has had to be up late at night, and has had very much washing to do for many years. The kitchen in which she is most of the time is damp, and opens into a yard into which she has often to go. About two years ago she thought that she hurt herself in lifting something, and soon after this, on putting her hands from hot into cold water, suddenly felt a numbness in both forearms. One year ago she noticed tremor in both hands and both legs. The tremor interfered with her work, and has increased. She also felt as if there were loss of power.

Present Condition.—The face is expressionless and looks as if it wore

a mask. She articulates without using her lips to any extent, and speaks in a low tone, scanning the syllables. The head is held stiffly, and the attitude of the whole body is peculiar.

The tremor is fine, and is constant while the hands are at rest. On voluntary effort the tremor ceases. On examination with the dynamometer, right hand 95° , left hand 80° . She feels weak generally, and says she cannot use her hands even to button her clothes or to dress or undress without aid. She performs all movements slowly and with great deliberation. The patellar reflex is not excessive.

Sensation.—She has lost the sense of numbness she used to have, but says she cannot feel a needle between the fingers when she attempts to sew. There is loss of sensation in the finger-ends; the compass points are not felt at less than three lines.

Her walk is slow and deliberate like all her movements, and there is no festination. Her eyes were examined, and there was no decided change in the fundus and vision was about normal. Pupillary reflexes good.

This patient was under observation for several months, and steadily grew worse. One peculiar feature was observed, however: it was that at one time the tremor almost ceased, although all of the other symptoms were worse.

ETIOLOGY.—As already mentioned, the causes which have been observed are fright or sudden grief and prolonged exposure to cold and dampness. A number of cases of the former are mentioned by Charcot, and a case which I have related above is a good illustration of paralysis agitans produced by fright. When caused in this way the disease does not present any peculiar features in its progress or termination. I have seen many cases in which the disease had been preceded by more or less exposure to dampness. One of my patients had worked in a basement room which was damp; another (Case II.) was a great deal of the time in a kitchen which opened on a wet yard, and she was constantly going in and out of doors, getting her feet wet frequently. Sometimes irritation of a peripheral nerve seems to have been the origin of the trouble. Charcot quotes several cases of this kind.

Sex does not appear to exert any special influence in the production of the disease. Some writers assert that it is more common in males than in females, but Charcot in his large experience at La Salpêtrière has not found this to be the case.

MORBID ANATOMY.—A number of autopsies have been made in cases of paralysis agitans without any constant lesion of the nervous system having been discovered. Charcot refers to three cases in which he made careful post-mortem examinations in which the results were negative. Parkinson and Oppolzer each report one case in which was found induration of the pons, medulla, and cervical portion of the cord. More recently, however, Charcot and Joffroy have examined cases in which microscopic examination revealed blocking up of the central canal of the cord by increase of the epithelium of the ependyma and pigmentations of the ganglion-cells.

Leyden has reported a case in which the disease was confined to the right arm, and on post-mortem examination a tumor of the left optic thalamus was found.¹

¹ Quoted by Hamilton, *Diseases of the Nervous System*, p. 500.

Dowse and Kesteven found degeneration of the nerve-cells of the anterior pyramids, changes in the olivary body, nucleus of the ninth nerve, laminae and corpus dentatum of the cerebellum and of the anterior cornua of the spinal cord. Also cortical sclerosis of the right lateral column of the cord and miliary changes in the white matter of the corpus striatum and hemispheres.¹

In this disease, as in chorea, there must be two classes of cases—those in which there is no lesion to be discovered after death, and others in which there are changes throughout the brain and spinal cord more or less widespread. The cases in which the disease comes on suddenly from some moral shock probably belong to the former class; while in cases which have come on gradually during senility one would expect to find organic changes in the nervous system. Ross² suggests that the cause of the tremor is probably a diminution in the conductivity of the fibres of the pyramidal tract, which prevents impulses from the cortex reaching the muscles in sufficiently close proximity to produce a continuous contraction. This, however, does not explain the cause of the tremor in the cases where it began suddenly from fright.

DIAGNOSIS.—The only diseases with which paralysis agitans may be confounded are disseminated sclerosis, senile tremor, and chorea in the aged. From senile tremor it may be distinguished from the fact that it begins before old age—that the tremor is more excessive and the gait and facial expression are distinctive. Chorea in old persons resembles paralysis agitans, but is not progressive, the tremor is not lessened as a rule by voluntary effort, and the peculiar gait and expression of the face are wanting.

There are many points of difference between paralysis agitans and disseminated sclerosis, as can be seen below :

| PARALYSIS AGITANS. | DISSEMINATED SCLEROSIS. |
|---|--|
| Tremor ceases on voluntary effort, or is not increased by it. | Tremor induced by muscular effort, and ceases during repose. |
| Tremor regular and fine. | Coarse tremor, becoming more so during voluntary effort. |
| Face expressionless; tremor of face rare. | Facial muscles affected; nystagmus frequent. |
| No tremor of head. | Tremor of head generally present. |
| Belongs to advanced age. | Usually comes on before middle age. |
| Propulsion (festination) and retrogression. | Staggering walk. |

TREATMENT.—The results of treatment are not encouraging. Cases have been reported in which cures were effected, but it is doubtful if they were true instances of paralysis agitans. Hyoscyamus and conium have been given with temporary relief to the tremor. Trousseau recommends strychnia, but Charcot declares that it aggravated the cases in which he gave it. Hammond advises the use of galvanism, at the same time giving strychnia or phosphorus. I have seen one case in which decided relief was obtained from arsenic hypodermically, and another in which the patient was benefited for a long time while taking small doses of strychnia combined with iron and quinine, and at the same time static electricity was applied.

CHOREA.

By WHARTON SINKLER, M. D.

CHOREA, or St. Vitus's dance, has been known for years, and the literature of the subject, especially among the older writers, is as extensive as that of any other disease.

It has been recognized by a variety of names, some of the most common being derived from some saint who enjoyed a popular reputation of power to cure the disease. For example, it has been called St. John's dance, St. Guy's dance, St. Modestus's dance, and St. Anthony's dance. Besides these names it has been termed ballismus, paralysis vacillans, epilepsia saltatoria, and orchestromania.

It will be observed that almost all of the names which have been applied to the disease relate to a dancing movement. This arises from the fact that the first notice of the affection dates back to the fourteenth century, when a kind of religious mania appeared in Southern Europe in the form of an epidemic. It was characterized by excessive dancing and gesticulatory movements, and affected large numbers of people at a time. In 1375 an epidemic which arose was spoken of as St. John's dance, and in 1418, in another outbreak of the disorder which occurred at Strasburg, by the order of the authorities those suffering were conducted in troops to the chapel of St. Vitus in Zabern, and there masses were said and other religious ceremonies performed for its cure.

We are informed that St. Vitus removed from Sicily when a boy, at the time of Diocletian's persecution of the Christians in the year 303, and suffered martyrdom in Florence in company with Crescentia and his tutor, Modestus.¹

Von Ziemssen states that as a pandemic disease the dancing mania died out in the fifteenth century, but that traces have remained on the Rhine up to the present time.²

In our own country there have been many epidemics of the same disorder on a small scale, and we may regard the Shakers as representing a type of the dancing mania. Weir Mitchell reports³ an outbreak which occurred quite recently in a children's asylum in Philadelphia. Prompt measures and separation of those affected from the well children checked the disorder, which at one time threatened to spread through the entire institution.

¹ "Hecker's Epidemics of the Middle Ages," *Sydenham Society's Transactions*, contains full details of these outbreaks.

² *Cyclopædia of the Practice of Medicine*, vol. xiv. p. 416.

³ *Lectures on Nervous Diseases*, p. 69.

These epidemics were quite different from what we now call chorea, and the individuals suffering were clearly affected by a psychical disorder of an hysterical form. In time, however, the name has come to be applied to a systematic disease characterized by irregular spasmodic movements of the limbs and other parts of the body.

The disease has been divided by some writers into chorea magna and chorea minor. The former, however, as described, is only an aggravated variety of hysteria, and need not be considered in connection with this subject.

Although the name chorea does not correctly describe the disease under consideration, it has been used for so many years that it is more convenient to retain it.

DEFINITION.—Chorea, as we now understand it, is a spasmodic neurosis, characterized by constant involuntary and irregular jerkings and twitchings of muscles or groups of muscles, which, in the majority of cases, cease during sleep, and are accompanied by more or less psychical disturbance in most instances.

ETIOLOGY.—Hereditary influence in the production of chorea is more or less marked. In some cases the connection seems to be remote, but in many instances it will be found that one of the parents has suffered from some form of nervous disease or has inherited a nervous diathesis.

George Huntington of Pomeroy, Ohio,¹ has recorded some remarkable instances of hereditary chorea. The affection, as he describes it, differs in many features from chorea as ordinarily met with, but it is apparently the same disease. It is found in the eastern end of Long Island, and has been studied in several generations by Huntington, his father, and grandfather. This part of Long Island is remarkably free from the usual type of chorea, none of these physicians having ever met with an example of it. The hereditary chorea is confined to a few families. It occurs more frequently in males than in females, and never attacks the patient until after middle life. It comes on gradually and takes years to develop, but when once established it yields to no form of treatment. In most cases there is a marked tendency to insanity and suicide in the later stages of the disease.

Some additional cases of hereditary chorea have been lately recorded by Peretti in No. 52 of the *Berliner klin. Wochenschrift*, 1885, and others by Clarence King in the *New York Medical Journal*, vol. i., 1885. The history of all these cases is strikingly like those of Huntington, and establishes without question a distinct form of chorea.

Mrs. N., one of Peretti's cases, had a mental affection with choreic movements, and there was a history of a similar condition in her parents and grandparents. Two of Mrs. N.'s four children, Mrs. A. and Anton N., had chorea in adult life; some of these became insane. Mrs. A. had five children; three of these became choreic; one had tremors and one became insane. Anton N. had ten children; of these six had chorea. In all of Peretti's cases the disease came on after the age of forty years, and persisted. In several members of the family insanity was associated with the chorea.

In the families where it occurs the nervous temperament predominates. It sometimes will be found that neither of the parents of the patient has

¹ *Medical and Surgical Reporter*, April 13, 1872.

had chorea or any other nervous disease, but that an uncle or an aunt has had St. Vitus's dance in childhood.

Chorea may occur at any period of life, from infancy to extreme old age. I have reported two cases in patients over eighty years of age¹—one at eighty-two and the other at eighty-six—who had characteristic attacks of St. Vitus's dance. Robert Saundby has collected twelve cases of chorea in the aged. The two cases just referred to are included in the number. He considers the affection very rare in old persons.² The following case is an example of congenital chorea, and I believe this to be very unusual. The movements of all infants are choreic, so that it is difficult to say when the chorea begins; still, it seems fair to infer that when a child has never had any but choreic movements it is a case of congenital chorea:

Case. I.—Jennie W——, aged nineteen years. Family history is good as regards nervous diseases. Her mother was frightened by seeing a case of chorea some time before the child was born. The movements were observed at birth, and have continued always. The patient was brought to my clinic at the Infirmary for Nervous Diseases, and her condition noted as follows: The movements are general and continuous; the arms and legs are in constant motion, and the mouth is perpetually grimacing; there is tremor of the tongue when it is protruded; volitional efforts increase the movements; during sleep they cease entirely; tendon reflexes are normal; there is no paralysis; heart-sounds are normal and the general health is good; menstruation is regular, and the choreic movements were not influenced in any way at the time of its first appearance.

Chorea occurs most frequently during the period of approaching puberty. See in an examination of 531 cases found 453 between the ages of six and fifteen years.

I have examined the notes of 282 cases of chorea, most of which are in the case-books of the Infirmary for Nervous Diseases; the rest are from my own note-books. Of the 282 cases, 217 were between six and fifteen years. They were distributed as follows:

| | | |
|----------------------|---------------------|---------------------|
| Under 1 year . . . 2 | At 7 years . . . 23 | At 16 years . . . 6 |
| At 2 years . . . 6 | 8 " . . . 24 | 17 " . . . 10 |
| 3 " . . . 4 | 9 " . . . 31 | 18 " . . . 5 |
| 4 " . . . 7 | 10 " . . . 23 | 19 " . . . 5 |
| 5 " . . . 9 | 11 " . . . 18 | 20 " . . . 1 |
| 6 " . . . 24 | 12 " . . . 25 | 21 " . . . 3 |

At 22, 25, 27, 28, 35, 38, 82, and 86 years, each 1 case.

Sex exerts considerable influence on the disease. See states that three-fourths of all the cases observed in the Children's Hospital in Paris occurred in girls. Of 328 cases which I have examined in reference to this point, 232 were females and 96 males.

Social condition has little or no effect on the production of chorea, but it is more common in cities than in the country. Indeed, everything which increases the excitability of the nervous system during development adds to the tendency to the disease.

West and Hamilton point to over-study as a cause, and I have frequently verified their observations. The annual examinations at our public schools give a number of cases of chorea.

¹ *Journal of Nervous and Mental Diseases*, July, 1881.

² *Lancet*, Nov. 24, 1884.

A. McLane Hamilton¹ has recently investigated the frequency of St. Vitus's dance among school-children in New York, and found that 20 per cent. of the children in the schools were affected with some variety of the disorder.

Rheumatism is certainly a predisposing cause, in my experience, but I have not found it associated with chorea as frequently as some authors have. In 279 cases which I examined with regard to this question, there was a clear history of rheumatism in but 37. Cardiac complications were much more frequent. In 82 cases there was a cardiac murmur heard. In some of these the murmur was no doubt anæmic, but in the majority there had probably been a rheumatic endocarditis. Many cases in which there is said by the friends of the patient to have been a previous attack of acute rheumatism, on investigation are found not to have had articular rheumatism, but merely some muscular or joint pains which were not inflammatory. Quite recently Joffroy and Saric have expressed the opinion that the pains in the joints during an attack of chorea are to be regarded as choreal arthropathies of nervous origin.

English and French writers have observed the relation between rheumatism and chorea in a large proportion of cases. Hughes and Burton Brown² found that in 104 cases which they examined as to rheumatism and affections of the heart, there were but 15 in which some rheumatic condition had not preceded the attack or a cardiac murmur did not exist.

Sée and Roget consider the causal relation between the two diseases so close as to make their connection almost a pathological law.

On the other hand, Steiner made quite opposite observations in Prague. He saw among 252 cases of chorea only four which originated during the course of acute articular rheumatism.³ This statement does not prove the absence of a relation between chorea and rheumatism, for Steiner does not say what proportion of cases occurred after an attack of rheumatism which had taken place some time previous. Hammond⁴ believes "that the influence of rheumatism upon chorea is not greater than that of a depressing agent to the organism."

Octavius Sturges, physician to the Hospital for Sick Children, Ormond St., London, says that in two years 219 cases of chorea have been treated at that institution: 20 per cent. of them were connected with rheumatism, but he does not believe in the rheumatic origin of the disease, because 15 per cent. of all children have rheumatism.⁵

The following cases illustrate the direct sequence of chorea upon acute rheumatism:

Case II.—Kate S——, æt. 17 years, came under my care in May, 1877, with an attack of acute rheumatism which lasted for two weeks. She regained strength slowly, and about June 11th, not more than two weeks after the subsidence of the rheumatic symptoms, choreic movements were noticed in the right arm. The movements were constant, and were worse when she was conscious of being observed. She often dropped things. The right leg jerked often and gave away under her in walking. Under the use of liq. arsenici bromidi the patient was entirely well in one month. A sister had had chorea.

⁴ *Dis. of the Nervous System*, p. 715.

Case III.—Rudolph C—, æt. 5 years, was placed under my care May 12, 1883. He has had scarlatina, and in Dec., 1882, he had an attack of inflammatory rheumatism, accompanied with slight choreic movements, from which he recovered in a short time. Three or four weeks before coming under my charge he had a return of rheumatism from getting his feet wet, and at the same time choreic trouble began again. He rapidly became worse, and in a short time was utterly helpless. On examination he is found unable to sit up or make any voluntary movements. He is unable to move the legs on account of the intense pain in the knees and ankles from the rheumatism. These joints are swollen and red. The right arm is in constant and violent motion, swinging about or thrashing up and down. The left arm lies motionless, and, although painless, he seems unable to move it. The fingers are clenched, and they are continually and rhythmically being pressed against the palm. He cries if an attempt is made to open the fingers. The facial muscles are contorted all the time, and there is a peculiar vermicular movement of the upper lip. He cannot speak a word nor can he protrude the tongue. He sleeps but little, and during sleep the movements are occasionally seen. He is very fretful and irritable, but is perfectly intelligent. The appetite is poor. Bowels regular; urine phosphatic and contains no albumen. There is a loud but not harsh cardiac murmur heard at the apex, replacing the first sound of the heart. Temperature, May 12, evening, 100° ; May 13, morning, $100\frac{2}{3}^{\circ}$. Pulse, 140. He was ordered *sodii salicylat.*, gr. v. q. q. h., and inunctions of cod-liver oil.

On May 18 the rheumatism was so much better that the salicylate was stopped and Fowler's solution of arsenic was given instead. The chorea had also become better. The arsenic was continued in increasing doses, and the case convalesced steadily. On June 26 he was able to return to his home in Maryland entirely well.

He remained well until July, 1884, when he had a slight attack of chorea, which was preceded for about a week by rheumatism. The cardiac murmur, which was almost absent after recovery from the first attack, was now heard again, but faintly.

Scarlatina is sometimes the forerunner of an attack of chorea. Other diseases, whooping cough or measles, may also be the immediate cause of an attack of chorea, but it is generally in cases where there is a predisposition to the disease.

The connection between pregnancy and chorea is of great interest. Barnes¹ has collected 58 cases, and Bodo-Wenzel² has added 8 more, making 66 in all. Of 51 of these patients, 31 were primiparæ, and in the majority of cases the ages were between twenty and twenty-three years. Four cases which came under my own personal observation were all young primiparæ, and were between the second and fourth months of gestation when the disorder began. The affection usually appears in the first half of pregnancy. It may cease before the eighth month or may continue to the end of gestation. Sometimes it persists after delivery. It does not necessarily occur in patients who have had the disease in childhood, but from the above cases it would seem that an attack in one pregnancy would tend to its recurrence in another. Of the 66 cases, 14

¹ *Obstet. Transactions*, vol. x. p. 147.

² *Ziemssen's Cyclopædia*, loc. cit., p. 428.

had had chorea in previous pregnancies. Sometimes the chorea appears only at the time of labor.

The immediate cause of chorea in pregnancy, when a cause can be found, is most often fright or rheumatism. In two of my own cases the patients were unmarried. Of the 66 cases of Barnes and Wenzel, fright is named as a cause in 7, and in 7 more rheumatism and endocarditis are stated to have preceded the attack.

Climate has been supposed to have a marked influence upon chorea. It was thought to be less frequent in warm than in cold regions; but Hirsch denies this, and Weir Mitchell¹ states that it does not appear to exist to any less extent in the southern than in the northern portion of this country.

Season, according to Mitchell,² largely affects the production of chorea. He has gone to great pains to collect statistics on the subject. He shows that the majority of attacks in his cases occurred in spring. This agrees with Wicke,³ who found that among 35 relapses, 13 were in spring, 12 in winter, 9 in autumn, and 1 in winter. On the contrary, Hammond⁴ found 54 attacks in the six months from October to March, and but 28 in the remainder of the year. Gerhard⁵ in a study of 80 cases found that of 68 attacks, 39 occurred in spring, 10 in summer, 7 in autumn, and 12 in winter. In Mitchell's cases a study was made of 170 attacks. In the spring and summer months there were 115 attacks against 55 in the winter and autumn months. This observer does not find that rain or dampness has any notable effect in causing the disease, but that the influence of storms is probably great.

Mitchell has written upon the relation between race and chorea. He states that in answer to a circular bearing on this question, sent out by the Smithsonian Institution, he has received a large number of letters from physicians in our Southern States and the West Indies. The general testimony was that chorea is rare among negroes.

Among the exciting causes of chorea are fright or mental apprehension of some kind. Of my 279 cases, 44 were ascribed to fright.

Malaria has been pointed out as influencing the production and course of chorea. Kinnecut has reported some cases in which the movements were aggravated with a certain periodicity.

Chorea may also be brought on by reflex irritation from nerve-injury. In a case which I saw in the practice of John H. Packard several years ago there was an injury to one of the digital nerves of the thumb from a splinter, which was the apparent cause of an attack of chorea; a portion of the nerve was excised, and the chorea ceased in a short time.

I have lately seen a case in which an attack of chorea came on apparently in consequence of a severe mash of the finger. The finger had been crushed by the runner of a sled, and the choreic movements began before the wound was healed.

Hamilton⁶ has found chorea associated with eczema. He saw a case in which eczema of the calves of the legs and of the scalp developed at the same time with an attack of chorea. Both got well about the same time.

SYMPTOMS.—An attack of chorea is usually preceded by more or less failure of the general health and evidences of some mental disturbance. It is quite common to be told by the parents of a child suffering from chorea that the little patient had seemed unwell for some time previous to the attack; that the appetite had failed, and that the child had looked pale; that he had been irritable or excitable, and at school the teacher had complained of restlessness or inattention in the pupil. In a little girl who was brought to me recently with her second attack of chorea her mother stated that for several days before the outbreak the child had been in excessive spirits, and that she had been singing loudly and in a peculiar manner. The same symptoms had preceded the first attack. Sometimes nothing is observed until it is found by the parents or teacher that there are abnormal twitchings and movements of the limbs.

At first there is a general restlessness and fidgetiness. The child may be punished at school for not keeping still or for dropping things. Soon irregular movements of groups of muscles are seen. The shoulder is shrugged or the fingers move spasmodically. At first the patient is aware of the movements and tries to control them, but before long the twitching and jerking are constant, and extend to most of the voluntary muscles of the body. He is then unable to control them for any length of time.

The sudden jerk of a limb followed by an odd grimace, the quick protrusion of the tongue, and the rolling of the eyes or snapping of the lids give a characteristic picture which can hardly be mistaken.

The extent of the movements varies in different cases. In some they are slight and affect only certain muscles. Often the disorder is confined to one lateral half of the body. In other cases the movements involve all the limbs and the trunk, and are so violent and constant that the patient does not seem to have a moment's rest. The trunk may be suddenly drawn backward, then the arms are extended or thrown up, and the legs flexed and tossed about with great quickness. Sometimes the patient is thrown off the bed or from the chair on which he may be to the floor.

The speech is often affected. The patient speaks in a thick or jerky manner, as if the tongue were too large for the mouth, and saliva usually flows in great quantities. Sometimes in bad cases there are involuntary utterances made at frequent intervals.

The features undergo contortions continually, and when at rest relapse into a condition of vacancy which makes the patient look almost idiotic. The expression of a child with chorea is so peculiar that the disease may almost be diagnosticated by this.

During sleep the movements usually cease, but generally the patient is restless while asleep, and in some instances the irregular movements continue even at this time.

The mental condition commonly shows some change. The child is irritable and peevish, cries and laughs readily, or is sullen and morose. Sometimes he is violent to those about him, but this is rare. Intellectually the patient suffers somewhat. He is not able to study as before, and the memory may be impaired. Sometimes there is a mild form of dementia.

During the course of the disease there may be exacerbations, and sometimes after convalescence has seemed established there are relapses.

Recovery is gradual, and as the abnormal movements cease the mental condition improves, and the patient regains his health without any traces of the disease remaining.

We will now consider some of the symptoms separately. First, as to disturbances of motion. As before remarked, the disorderly movements occur soon after the general restlessness is seen. They most commonly begin in one upper extremity. The hand is thrown into various positions, the fingers are flexed and extended or separated, and all of the movements occur with great rapidity. In a day or two the whole arm is affected, and then the leg of the same side is involved in the jerking and twitchings. In many cases the facial muscles are contorted, the mouth is pursed up or opened wide, and then quickly twisted into some other shape. If the patient is told to put out his tongue, it is protruded after a moment's hesitation, and then suddenly retracted, the jaws coming together with a snap. A smacking sound is made with the lips quite often, and words are uttered involuntarily. The movements may remain confined to one side of the body, constituting what is called hemichorea. This is quite common, and the right side is rather more frequently involved than the left. There is so great difference of opinion among authors on this point that it is probable that one side is affected about as often as the other. Of 252 cases which I have examined, 69 were right and 43 left hemichoreas. Gerhard¹ found in 80 cases of chorea that 32 were unilateral; of these 20 were right and 12 were left. Sée, however, found that in 97 of 154 cases the movements were either confined to the left side or were more marked on that side. He states that in his experience the proportion between left and right hemichorea is as 37 to 27. Pye-Smith in 33 cases of unilateral chorea found 15 on the right and 18 on the left side. Many cases which begin as hemichorea soon become general.

The disease reaches its greatest severity in about two weeks, and if the case is a bad one we find by this time all of the voluntary muscles are in constant movement. At this time the French name for chorea, *folie musculaire*, is most appropriate. Patients are often unable to walk or to sit up, and sometimes they may be thrown from the bed by violent spasmodic movements of the trunk. Strange as it seems, patients rarely complain of fatigue, notwithstanding the violent muscular exercise. This is probably because each set of movements is of short duration and is constantly changing its seat.

As a rule, the movements cease completely during sleep or under an anæsthetic. Sometimes occasional twitchings of muscles are seen in sleep, and in rare instances we are told by the parents of a child with chorea that the movements are as active in sleep as in the waking hours.

The movements of chorea occur either while the limbs are at rest or under the influence of voluntary effort. This fact has been pointed out by Mitchell and by Gowers. In some cases the movements are most marked when the patient is at rest. If a directed effort is made to use the member for a time, the choreic movements are suspended. For example, a patient may be able to carry a glass of water to the mouth without

¹ *American Journal of Med. Sci.*

spilling a drop, while a moment before the hand may have been performing a continual dance. I have often observed that while the limb to which the whole attention has been directed in performing some movement has been steadied, the other limbs become violently agitated.

In another class of cases the movements are comparatively slight when the part is at rest, but when a motion is attempted the disorder of the muscles is so much increased that it is almost impossible for the act to be completed. The patient is told to pick up some small object: he throws the hand out toward it, and it is jerked away before he can grasp it. He again puts the hand forward, reaches the object, and the fingers open and shut and sprawl over the article before it is taken up. Sometimes it cannot be grasped at all. This has been called choreic ataxia, but it is only one type of the cases commonly seen.

This brings us to the influence of the will on the movements in chorea. There are some cases, as mentioned above, in which the movements may be controlled by the will for a brief period, but they will sooner or later return. In other cases it is quite impossible for the patient to check the movements at all, and one frequently sees in a case of hemichorea the sound hand used to grasp the other, so as to control the movements. We have referred to this because of Niemeyer's opinion that corporeal punishment would shorten an attack of chorea.

Chorea is sometimes confined to a single muscle or group of muscles. When limited in this way it is generally in the head, face, or perhaps in the shoulder. These cases of localized chorea have been spoken of by Mitchell as habit chorea.¹ They are often very obstinate in resisting treatment, and sometimes last during life.

PARALYSIS.—Not infrequently in chorea there is paralysis to a greater or less extent. It is generally one-sided, and most often involves the upper extremity. The limb affected is the one in which the movements were most violent. The arm may hang entirely powerless or it may be only enfeebled, and feeling to the patient like a dead weight. The paralysis always recovers with the chorea or soon after.

POST-PARALYTIC CHOREA.—Under this term Mitchell and Charcot have described a variety of chorea which is seen in patients after an attack of hemiplegia. The movements are chiefly on voluntary effort, and are those of inco-ordination. They come on from one to several months after an attack of unilateral paralysis, and are sometimes seen in cases in which almost complete recovery has taken place. Mitchell has reported² a case which was under my care for several years, and which he saw in consultation with me. This patient had two attacks of left hemiplegia, the last being fatal. After the first attack there was great gain of power to use the arm and leg, but the movements were performed awkwardly and with an irregular jerking movement. A post-mortem examination revealed a spot of softening the size of a filbert in the left corpus striatum, which was apparently recent, and a point of red degeneration in the right crus cerebri. The vessels at the base of the brain were extensively atheromatous.

Of the electrical condition of the muscles in chorea but little is known. Rosenthal³ found increase of faradic contractility in three cases of hemichorea, and the galvanic test showed a high degree of excitability, dem-

¹ *Lectures on Nervous Diseases*, p. 146.

³ *Ziemssen's Cyclopaedia*, loc. cit., p. 434.

² *American Journal of the Med. Sci.*

onstrated by the fact that weak currents gave contractions at cathodic closure, or even tetanic contractions, and also contractions were produced at cathodic opening.

The affection of speech which is so common in chorea is due to disordered action of the laryngeal muscles, or it may be from choreic action of the abdominal muscles. Sometimes it is chiefly from the awkwardness of the tongue. The usual form of trouble is that the patient speaks in a staccato manner and the syllables seem as if they were driven out. When the chorea is in the laryngeal muscles, the tone and pitch of the voice are altered.

Chorea of the heart is sometimes spoken of, but it has never been satisfactorily demonstrated that there is any real disorder of cardiac rhythm in chorea. It is not unusual in chorea to meet with over-action or palpitation of the heart, but these conditions do not necessarily depend on the disease.

Valvular murmurs are often met with from the beginning of an attack. In some instances they are the result of an endocarditis, but frequently they are functional or anæmic. They are usually heard at the apex. Sometimes there is a reduplication of the first sound, giving the idea of a want of synchronism in action of the two sides of the heart; but this is probably not the result of chorea of the heart. I recall one patient, a child of seven or eight years, in whom the reduplication of the first sound was very distinct during an attack of St. Vitus's dance. She was brought to me at the beginning of a second attack a year later, and the reduplication of the cardiac sounds was heard again, so it is likely that it had continued during the interval, and was probably a congenital condition.

The pupils are commonly dilated in chorea and respond sluggishly to light.

REFLEXES.—I have examined the condition of the patellar reflex in 50 cases. In 26 of these it was present in normal degree, in 15 it was diminished, and in 9 it could not be excited. In one patient it was absent during the height of the choreic movements, but could be readily produced after the patient had recovered. The condition of the reflexes has also been examined by Joffroy and Saric,¹ and they found that of 16 cases of chorea the reflexes were abolished or diminished in 12.

SENSIBILITY.—Authors state that disorders of sensation are met with in chorea, such as localized anæsthesia or a general hyperæsthesia: I have never met with any such instances. Patients often complain of pain in the joints or in the limbs, and this may be unaccompanied with swelling or tenderness on pressure. Tenderness on pressure over the vertebrae is rare in my experience, although others speak of its being of frequent occurrence. Mental disorders are generally present, but only to a slight extent. There is almost always irritability of temper and peevishness. The most sweet-tempered children become cross and perverse, laugh immoderately at trifling things, or cry as readily if they are annoyed. There is generally failure of memory and incapacity for study or thought. In most cases, however, this exists to so slight an extent as not to be noticed except on very close observation. Sometimes there is marked mental disorder amounting almost to imbecility, and occasionally the mental weakness remains for some time after the motor disorders have recovered.

¹ *L'Union médicale*, Sept. 22, 1885.

The condition of the pulse is generally unchanged, but sometimes it is abnormally frequent. The temperature, according to Von Ziemssen, is unchanged.

The nutrition generally suffers. The patient rapidly loses flesh, and becomes anæmic; the skin grows dry, and the hair gets harsh. The digestion is apt to be disordered. The tongue is large, pallid, and coated thickly, and there is sometimes nausea or vomiting. The appetite is not good. The bowels are often constipated. The urine has been examined by several observers. Bence Jones found an excess of urea at the height of the disease. Albumen is not present except accidentally, but there is usually an excess of phosphates. In several cases in which we have examined the urine at the Infirmary for Nervous Diseases we found that the specific gravity was high while the chorea was at its height, but fell to normal as the patient recovered.

Chorea is spoken of as acute and chronic, but all cases are more or less chronic. Those cases which last eight or ten weeks may be considered acute, while those running on for months or years are properly called chronic.

DURATION.—Considerable difference of opinion exists as to the duration of chorea. Some writers speak of three or four weeks as an average attack. Gray and Tuckwell, in a series of cases treated by the expectant plan,¹ found an average duration of ten weeks. Occasionally a patient is seen with an attack of chorea which lasts only a few days. The parents of a little patient whom I saw a few days ago assured me that her second attack lasted only a week. They are educated and intelligent persons whose statement can be relied upon.

The course is not always regular. In some cases the disease gradually reaches a crisis, remains stationary for a few days, and then by degrees declines; in others there are exacerbations. The patient will seem to be almost well, and then become very much worse for a time. Relapses are not infrequent, and are generally caused by fright or excitement.

The recurrence of attacks of chorea is well known. A child who has had the disease one year may have it a second or third year. It is most likely to recur in the spring. Some cases have as many as five attacks, but as puberty approaches the attacks are lighter, and finally cease. Of 282 cases to which I have referred, 198 were first attacks, 47 had had chorea twice; 23 were in their third attack, 8 in the fourth, and 3 in the fifth attack.

TERMINATION.—The disease in most instances terminates in complete cure, but sometimes there is nervousness or want of co-ordination remaining for a time. Rarely the inco-ordination or a certain quickness in movement becomes permanent.

Death is a rare termination of chorea except in pregnancy. If it does occur, it is usually from some complication. In pregnancy the mortality is great. Of 64 cases collected by Wenzel, 18 died. In Philadelphia, in seventy-four years from 1807 to 1881, there have been but 64 deaths from chorea; of these, 38 were under twenty years, and 26 over that age.

Hutchinson reports a fatal case in a boy of twelve years.² After complaining of headache and rheumatic pains for several days, choreic move-

¹ *Lancet*, Nov. 28, 1876.

² *Philadelphia Med. Times*, vol. vi. p. 535.

ments began. They soon became general and very violent. At the end of two weeks he was admitted to the Pennsylvania Hospital. At this time the patient was so extremely convulsed that it was impossible to keep him in bed without tying him. The movements continued but little abated, and the child died in two days.

Another case of unusual interest is reported by Hunt.¹ The patient, a man of twenty-nine years, had suffered from chorea of the face and arms for years. In consequence of a fall on the pavement he fractured the left humerus. The movements were immediately exaggerated, and in spite of a carefully adjusted splint it was impossible to keep the arm at rest. The fragments were in a state of constant movement, and the points of bone threatened to penetrate the skin. The skin was so much excoriated that it was determined to dispense with the splint and attempt to keep the limb at rest by the administration of morphia hypodermically in half-grain doses three times daily. This failed to keep the arm quiet, and the seat of fracture became greatly inflamed. No form of appliance or medication succeeded in keeping the arm at rest, and the patient finally sank and died from exhaustion on the tenth day after admission to the hospital. The post-mortem examination revealed no gross lesion of the brain or cord. No microscopic examination was made of the brain.

MORBID ANATOMY AND PATHOLOGY.—In a disease so seldom fatal as chorea it is not surprising that there have been but few post-mortem examinations made. In the earlier autopsies, before the microscope was extensively used, but little of value was recorded. Sée, who collected 84 cases in which post-mortem examinations were made, reported that in 16 no changes were found in the nervous system. In 32 there were lesions in the brain and nervous centres, usually softening and tuberculosis, and in the remainder inflammatory changes in the serous membranes. In 29 there were evidences of heart disease. Sée considered that but few cases of death in chorea were caused by inflammatory diseases of the heart, but that the majority should be referred to nervous excitement and anæmia.

Ogle² in a report of 96 cases of chorea mentions 16 which were fatal. Post-mortem examinations were made in all of these. Cardiac lesions were found in 13. In 10 of these deposits were found upon the valves, and in 3 there was some change in the pericardium. He speaks of having noted congestion of the nervous centres six times, and softening of the cord once.

In all of 11 autopsies reported by Pye-Smith³ there were cardiac lesions found. In every case old or recent deposits were observed upon the valves. In two instances the heart was hypertrophied, and in one there was pericarditis. Changes in the nervous system were less often found by this writer. In 1 case there was hyperæmia of the cord, and in 3 cerebral hyperæmia.

Dickinson found in 22 fatal cases of chorea 17 in which the heart was diseased. "In every instance making up the large tale of cardiac disease there were recent vegetations on the mitral valve, and often also elsewhere."

In the fatal case of Hutchinson referred to above the heart was found diseased, the aortic valves were incompetent, the leaflets being swollen

¹ *Pennsylvania Hospital Reports*, vol. ii.

² *Brit. and For. Med.-Chir. Review*, Jan., 1868.

³ *Guy's Hospital Reports*, 1874.

and softened, and the aorta was atheromatous above the sinus of Val-salva.

Of late years a number of careful autopsies have been made in cases of chorea. The brain and spinal cord have been closely examined, and in almost every instance some lesion has been found in both of these organs.

Steiner reported in 1868 the results of post-mortem examinations in 3 fatal cases of chorea. In 1 case he found cerebro-spinal anæmia, serous effusion into the spinal canal, and proliferation of the connective tissue in the upper part of the cord; and in another hyperæmia of the brain and cord.

Elischer,¹ who reports a fatal case in a parturient woman who had an attack of chorea in her eighth year, two in her sixteenth year, and another in a previous pregnancy, found at the autopsy hyperæmia and œdema of the brain and gray substance of the cord. Microscopically, the brain showed fatty, amyloid, and pigmentary changes in the nerve-elements and vessels of the large central ganglia, small secondary extravasations of blood in the connective tissue, and numerous emboli in the smallest vessels, especially in the cortex. In the spinal cord there was seen abundant proliferation of nuclei in the adventitia of the vessels. In the central canal serum was found, and the surrounding connective tissue was harder than usual.

Dickinson has contributed an excellent paper on the pathology of chorea.² He relates the particulars of the autopsies in 7 fatal cases in which he personally made microscopical examination of the brain and spinal cord. He also adds the results of post-mortem examinations in 17 other cases at St. George's Hospital and at the Hospital for Sick Children. In all of the 7 cases in which microscopic examinations of the brain and cord were made there were found hyperæmia of both of these structures, in many instances hemorrhages into the substance of the nervous tissues, dilatation of the smaller vessels, and in chronic cases sclerotic changes in the course of the vessels. "The first visible change," he remarks, "would seem to be the injection or distension of the arteries, succeeded by extrusion of their contents, to the irritation and injury of the surrounding tissue." The changes seemed to affect both brain and cord in all cases. The parts of the brain most constantly affected lay between the base and the floor of the lateral ventricles in the track of the middle cerebral arteries, the substantia perforata, the corpora striata, and the beginning of the Sylvian fissures. "Of the cord no region was exempt, but perhaps the cervical and dorsal regions were usually more affected than the lumbar. With regard to the vertical or physiological divisions of the cord, these all, whether white or gray, shared in the vascular destruction; this condition, however, was usually most marked in the vessels belonging to or in connection with the lateral part of the gray matter about the root of each posterior horn. And it is to be observed that this was also the chosen situation of the more definite and special changes, whether hemorrhagic (as in two instances), sclerose, or exudatory. Speaking generally, the chosen seats of the choreic changes are the parts of the brain which lie between the beginning of the middle

¹ *Cyclopædia of the Practice of Medicine*, Von Ziemssen, vol. xiv. p. 450.

² *Medico-Chirurgical Transactions*, vol. xli. p. 1, 1876.

cerebral arteries and the corpora striata—the *parta perforata*; and in the cord the central portion of each lateral mass of gray matter comprising the root of each posterior horn.”

The embolic theory of chorea has been held by several investigators, among them Hughlings-Jackson. It is undoubtedly an attractive and reasonable view, especially when we consider the large proportion of cases in which there is valvular disease of the heart. Dickinson, however, does not consider this hypothesis tenable. In none of the cases in which he made post-mortem examinations did he find evidences of embolism. “In none of the instances described were decolorized fibrin, detached clots, or signs of impaction detected, and the erraticism of embolic accident was wanting: the constancy indeed with which the changes repeated themselves in certain positions, and the equality with which they affected both sides of the body, are conclusive objections to this hypothesis. The corpora striata, for example, were affected with almost absolute symmetry, notwithstanding that these bodies receive their blood respectively from the right and left carotids and different parts of the aortic arch.”

Rheumatism is associated with or precedes chorea in a large proportion of cases, and this was pointed out by Kirkes in 1850 and again in 1863. This connection between rheumatism and chorea, and the frequent occurrence of endocarditis in chorea, has led some authors to believe that the endocarditis is always rheumatic, and that the chorea is the result of the endocarditis. Dickinson, however, points out that in cases in which there is a distinct history of the chorea beginning suddenly from fright there are often well-marked cardiac murmurs heard. He believes that in all cases of chorea in which there are cardiac murmurs they are due to endocarditis, and suggests that in these cases from fright the endocarditis is due to irregularity of cardiac action. This, of course, is mere hypothesis, and we must bear in mind that in all cases of chorea there is anæmia, and that the murmur may be purely functional.

H. C. Wood, in a communication read before the College of Physicians of Philadelphia,¹ gives his views of the pathology of chorea, based upon the results of post-mortem examinations made in a number of dogs who had the disease. He believes the history of chorea to be this: “Owing to emotional disturbance, sometimes stopping of various vessels of the brain, or sometimes the presence of organic disease, there is an altered condition of the ganglionic cells throughout the nerve-centres. If the cause is removed and the altered condition of the nerve-cells goes only so far, it remains what we call a functional disease. If it goes so far that the cells show alteration, we have an organic disease of the nervous system.”

In two dogs which were choreic the movements continued after section of the cord. This shows that in dogs, at any rate, the movements originate in the cord. In four instances of canine chorea in which Wood made autopsies there were found in the cords of three mild grades of infiltration of leucocytes in the gray matter. In the fourth, in which the dog had died of the disease, the ganglion-cells were degenerated, and in some places had disappeared. He concludes, therefore, that choreic movements may depend upon a diseased condition of the motor cells of the cord.

¹ *Philada. Med. News*, May 30, 1885.

Although there are several recorded cases of human chorea in which lesions of the spinal ganglionic cells have been found, we cannot believe that this can be a constant lesion in chorea. The disease is too transient in many cases, and presents too many variations and anomalies, for the cord to be always the seat of the diseased condition.

In an interesting paper read by Angel Money before the London Medical and Chirurgical Society in 1885 he detailed some experiments in which, by injecting a fluid containing arrowroot, starch-granules, or carmine into the carotids of animals, he produced movements closely resembling chorea; and this was found to be associated always with embolism of the capillaries of the cord. In the discussion which followed Broadbent and Sturges expressed their disbelief in the embolic origin of chorea in man. Hughlings-Jackson said that he held the view of the cerebral origin of chorea, one of his reasons being the frequency with which the face-muscles are affected in this disease.

The probabilities are that in chorea there is a disordered condition of the brain and cord more or less general. The lesions are no doubt slight in mild cases of short duration, but in severe cases of long standing there occur well-marked changes in portions of both brain and cord. We cannot do better than to sum up the pathology of chorea in the words of Dickinson: "A widely-distributed hyperæmia of the nervous centres, not due to any mechanical mischance, but produced by causes mainly of two kinds—one a morbid, probably a humoral, influence which may affect the nervous centres as it affects other organs and tissues; the other, irritation in some mode, usually mental, but sometimes what is called reflex, which especially belongs to and disturbs the nervous system, and affects persons differently according to the inherent mobility of their nature."

DIAGNOSIS.—The only diseases for which chorea may be mistaken are paralysis agitans and disseminated sclerosis. The former occurs only in adult life, and the tremor is of a regular rhythmical character. In the latter the tremor occurs only on voluntary effort, and is also more regular than the movements of chorea. There are forms of congenital sclerosis seen in children which closely resemble chorea. Here the duration of the disease and the association of contractures with it distinguish it from chorea.

Hysterical subjects have a form of chorea which can only be differentiated from the true disorder by noting the general hysterical character of the case and the result of treatment, which strongly influences the will-power of the patient.

PROGNOSIS.—In the great majority of cases this is favorable. If the disease occurs in childhood and is without complications, recovery generally takes place spontaneously after a few weeks. Should the movements be violent and continuous, so as to interfere with sleep and the taking of food, or should there be any complication, such as acute rheumatism or cardiac disorder, then the prospect of recovery is not so good.

The prognosis as to relapses should be given with caution. If in a child, it is possible that there will be a return of the disease after a longer or shorter interval. It is not likely to recur until after several months, usually at about the same season the following year. As the child grows older the intervals become longer, and it may safely be

asserted that after puberty is passed and bodily development completed there will be no more returns of the affection.

The cure is usually complete. It must be remembered, however, that for some time after an apparently complete cure there may be slight inco-ordination of movements, particularly in the arms and the face. These are shown in the unnecessary haste in making uncertain motions or in slight grimaces, or if excited an awkwardness in the use of the fingers.

Death is a rare termination in uncomplicated cases, especially in children. The fatal cases are generally when acute rheumatism has been associated with the chorea or when there has been a fracture or an injury as a complication.

In Sée's statistics there is a mortality of 5.7 per cent. in 158 cases in the Children's Hospital. In adults, and more particularly in pregnant women, death is more common. Wenzel's cases referred to above gave a mortality of 27.3 per cent.

The cause of death in chorea may be from the intensity of the disease, and in this case the symptoms are generally violent from the outset, increase to an extreme extent, and then collapse and coma come on. The movements may cease when the collapse occurs, but they may continue to the last, growing gradually less until death.

TREATMENT.—A vast number of remedies have been popular in this disease from all ages. The medicine which is most generally depended upon at the present day is arsenic. It is advised by most writers, and in my own experience is decidedly the most reliable remedy for chorea which we know. The best way to administer it is in the form of Fowler's solution, and it should be given in large doses. I have given the bromide of arsenic, but did not find it superior to Fowler's solution. The amount of arsenic which can be safely borne by children with chorea is surprising to those who have not had experience in its administration. The medicine should be given in gradually increasing doses until the toxic effects are well marked or until the patient is convalescing. In a child of six years three drops may be given to begin with, three times a day. One drop additional should be added to the dose each day, and the child soon acquires a remarkable tolerance of the drug. As much as twelve or fifteen drops at a dose is borne by a child of eight years. If vomiting or much œdema of the face occurs, the medicine should be stopped for a day or two, and then the original dose should be taken, to be again increased as before.

Seguin recommends that the patient should begin again with the dose at which tolerance ceased. For instance, if vomiting occurred after a dose of nine drops, he stops the medicine for a day, and begins again with eight drops. I have found that sometimes this causes vomiting again, and I think it preferable to resume the medicine with a small dose.

It is often seen that a patient becomes worse during the first few days that the arsenic is taken, but improvement generally begins after a week of the arsenical treatment, and is well marked after two weeks.

In obstinate cases it is of marked advantage to give the arsenic hypodermically. Cases which do not yield to the drug when given by the mouth often improve at once when it is given hypodermically. Chronic cases which have resisted all forms of medication sometimes are cured by

hypodermic injections of arsenic. For giving arsenic in this way it is best to use Fowler's solution, made without the compound spirit of lavender. It is less likely to cause abscess to form at the point of puncture.

Other remedies enjoy a reputation in the treatment of chorea. Sulphate of zinc is relied upon by many, and it is the means which Ross recommends. It should be given in increasing doses like arsenic, and very large doses may often be taken without disturbing the stomach. Trousseau, Hammond, and Hamilton favor strychnia, but I have had no experience in its use.

Cimicifuga and conium are both often beneficial in their effects. I have seen the former do good when arsenic had failed. Conium to be efficacious must be given in large doses. Eserine and hyoscyamine have both been successfully employed, the former by Bouchut, and the latter by Oulmont and Laurent. Recently, DaCosta¹ has reported, in a clinical lecture at the Pennsylvania Hospital, a case of very severe chorea successfully treated with hyoscyamine. The patient was a boy of eleven years, and the disorder had followed an attack of acute rheumatism. He was given $\frac{1}{100}$ gr. of hyoscyamine three times a day.

Ziegler² has recorded several cases which recovered under the use of nitrite of amyl. The bromides and chloral are useful adjuncts to treatment in case of sleeplessness or mental irritability. Cases of cure by the use of chloral alone have been reported. Bouchut gave a girl of fourteen and a half years, with chorea and dementia, 45 grains of chloral a day for twenty-seven days. She slept most of the time, but improvement was seen on the fifth day, and cure was completed on the twenty-eighth day of the use of the chloral. Electricity has been efficient in the hands of many writers. I have found galvanization of the spine to produce a quieting effect in some cases.

Iron is always of use in chorea; it may be given during the course of the disease, and is generally necessary in convalescence. Cod-liver oil or malt extract should be given in feeble persons.

It is scarcely necessary to mention the other remedies which have been recommended. DaCosta has used the bromide of iron. H. C. Wood has used a preparation of skunk cabbage, and there are a great number of other remedies which have been found of value.

Next to the internal means come external applications. Baths and frictions are useful in their effect on the general health. The ether spray to the spine or the application of an ice-bag for ten minutes once or twice daily is sometimes found to assist the other means. Cold douches have been advised by some, but they may do harm. The care of the general health of the patient is of first importance, and his surroundings should be as quiet as possible.

It is of the greatest value in bad cases to place the patient in bed and keep him there until the symptoms improve. John Van Bibber of Baltimore has treated a number of cases of chorea successfully by keeping them secluded in a darkened room. Such an extreme degree of isolation is not often necessary, and it might make a child more nervous.

In children the patient should always be taken from school and kept from exciting play. Plenty of fresh air and wholesome food should be

¹ *Philada. Med. Times*, Jan. 23, 1886.

² *Ibid.*, vol. vi. p. 486.

insisted upon. Change of air to the mountains or to the seashore often effects a cure in a short time.

Some cases do not appear to be benefited by any treatment. These are the hereditary form of chorea and some of the localized choreas. The latter are often helped or cured by the hypodermic use of arsenic even in long-standing cases.

ATHETOSIS.

BY WHARTON SINKLER, M.D.

THIS disease was first described by Hammond in his work on *Diseases of the Nervous System* in 1871, and cases have since been reported by many observers, among them Clifford Allbutt, Claye Shaw, Eulenburg, Oulmont, and Gowers. The disease is named by Hammond from the word *ἀθετος*, without fixed position.¹ The principal features are an inability to retain the fingers and toes in any position in which they may be placed, and the continual movements which persist in the parts—a condition called by Gowers mobile spasm.

Athetosis is often connected with impaired mental powers; many of Shaw's cases were in imbecile children.

The movements of athetosis are not confined to the hand in all cases, but they are sometimes met with in the foot, and even in the muscles of the face and back.

The following is Hammond's original case:² "J. P. R——, aged thirty-three, a native of Holland, consulted Hammond Sept. 13, 1869. His occupation was bookbinding, and he had the reputation, previous to his present illness, of being a first-class workman. He was of intemperate habits. In 1860 he had an epileptic paroxysm, and since that time, to the date of his first visit to me, had a fit about once in six weeks. In 1865 he had an attack of delirium tremens, and for six weeks thereafter was unconscious, being more or less delirious during the whole period. Soon after recovering his intelligence he noticed a slight sensation of numbness in the whole of the right upper extremity and in the toes of the same side. At the same time severe pain appeared in these parts, and complex involuntary movements ensued in the fingers and toes of the same side.

"At first the movements of the fingers were to some extent under the control of his will, especially when this was strongly exerted and assisted by his eyesight, and he could, by placing his hand behind him, restrain them to a still greater degree. He soon, however, found that his labor was very much impeded, and he had gradually been reduced from time to time to work requiring less care than the finishing, at which he had been very expert.

"The right forearm, from the continual action of the muscles, was much larger than the other, and the muscles were hard and developed like those of a gymnast. When told to close his hand he held it out at arm's length, clasped the wrist with the other hand, and then, exerting all his power,

¹ *Diseases of the Nervous System*, p. 722.

² *Ibid.*

succeeded, after at least half a minute, in flexing the fingers, but instantaneously they opened again and resumed their movements.

"In this patient there was impairment of intellect, his memory was enfeebled, and his ideas were dull. There was no paralysis of any part of the body, but there was slight tremor of both upper extremities. The involuntary movements were of the right arm, and continued during sleep. Sensation was normal. The spasm of the muscles causes severe pain in the arm, and keeps him from sleeping at night." Hammond used various remedies without relief, and had the patient under his charge for many years. Finally, he showed the patient to the American Neurological Society at the annual meeting in 1883, with almost complete relief to the movements as a result of nerve-stretching.

Athetosis is found in two forms—the hemiplegic and the bilateral varieties. In the former there has usually been an attack of hemiplegia more or less marked, or there has been an epileptic fit or unconsciousness from alcohol, as in Case I. There is often hemianæsthesia or some disorder of sensation. In the bilateral type the movements exist in all of the limbs, and are unaccompanied by weakness or disorder of sensation. The degree of movement varies in different cases. In some it is very slight, and can be controlled by extreme effort on the part of the patient. In other cases the movements are violent and uncontrollable. The muscles of the affected limbs become hypertrophied from the constant exercise.

The following case of athetosis has come under my care :

Case II.—W. A——, aged thirteen years, male. He had good health until 1877, when at the age of six years he had diphtheria. The attack was not severe, and he was up most of the time. About ten days after apparent convalescence he was suddenly seized with left hemiplegia. The paralysis was complete, involving the left arm and leg, the left side of the face, and the muscles of deglutition. There was also aphonia. In two weeks he began to talk, but indistinctly. In a month he could move the arm, but the movements were inco-ordinate. At about the same time he began to walk, but dragged the leg. The arm never regained power of voluntary motion, but instead there came on a spasmodic condition of the muscles which fixed the arm in various positions, and at the same time there were kept up constant but irregular movements of the hand and fingers. No spasmodic action of the leg-muscles occurred until a year later. He has never walked well since the attack of hemiplegia. The positions which the arm has assumed have varied at different times, but it usually retains one attitude for several months at a time. Sometimes the arm has been held in extension ; at another time it has been flexed ; indeed, the positions have been numerous. His general health improved and the speech became perfect.

Condition on examination Aug. 14, 1884: General health good, well grown for age. The nutrition of the affected side is good, but the left side of the face is markedly smaller than the right, although there is no paralysis. The position of the arm attracts immediate attention. The arm, hand, and fingers are in extreme extension, as shown in the cut, which is made from a photograph. The arm-muscles are tense and rigid. The fingers are continually in motion, sometimes flexed, sometimes extremely extended ; then in a few moments they will be widely separated or distorted in some other way. The favorite

position, however, seems to be with the fingers extended until bent backward, separated from each other, and the thumb adducted slightly. The patient is unable to bring the arm down by a voluntary effort, but when asked to put it by his side he pulls it down with the right hand, and keeps it down by sitting upon the hand. The muscles of the arm are hypertrophied, especially those of the upper arm and shoulder. The circumference of the left arm around the biceps is almost an inch greater than that of the right. The leg is stiff and the foot is usually inverted. Here also the position changes at different times. When he walks the stiffness increases and the foot is dragged. The speech is clear and distinct, and the intellect perfect. He goes to school, and is fully equal to or more advanced than boys of his age. There is no evidence of cardiac disease.

The patient's condition in Oct., 1885, had changed somewhat. The arm is in a different attitude. It is still extended, but is held down by the side or away from the body. At times the forearm is strongly supinated. There are still constant but slowly-changing movements of the fingers. One plan which the patient has of keeping the arm flexed is to put the forearm behind the back with the right hand, and it becomes locked there by the action of the extensors. By a strong effort of will he can slowly and with great difficulty open and shut the fingers, and can flex the forearm. The leg is in the same condition as before.

The resemblance between athetosis and post-paralytic chorea is very close. Most of the cases of the former disorder which have been reported have been of the hemiplegic type. In Case I. the disease came on after an attack of delirium tremens, which was followed by six weeks of unconsciousness. The first symptom the patient was capable of noticing was numbness of the right arm and leg. The involuntary movements came on later. This would look as if there had been some lesion involving the left hemisphere of the brain. It is stated that no paralysis existed when the case was examined by Hammond, but there may have been a slight hemiplegia which had passed away. In another case reported by the same author the peculiar movements were preceded by hemiplegia and aphasia.

Oulmont has written a complete essay on athetosis, and has collected therein all the literature of the subject.¹ He sustains the view of the close connection between athetosis and post-paralytic chorea, but he con-

FIG. 26

Case of Athetosis.

¹ *Étude clinique sur l'Athétose*, Paris, 1878.

siders that, although nearly allied, a difference does exist between the two affections. He believes this is most marked in the bilateral form of athetosis, for here the disorder is usually not preceded by paralysis, and it is not accompanied by disturbances of sensation.

Gowers¹ has also collected a number of cases, some of which came under his own observation, and has written a valuable treatise on the subject.

PATHOLOGY.—The symptoms point to a brain lesion, probably in the gray matter, and a perverted condition of the nerve-cells which leads to over-action, either spontaneously or under the influence of a motor impulse. In most of the cases reported by Clayc Shaw there was imbecility. Charcot found in three post-mortem examinations lesions in each instance in the posterior portion of the optic thalamus, the most posterior part of the caudate nucleus, and the most posterior part of the corona radiata. Gowers has made an autopsy in one case in which there was post-hemiplegic inco-ordination affecting the arm only, without the spasmodic fixation of the limb. In the brain was found but one lesion, and that was a cicatricial induration of the optic thalamus, extending across its centre beneath its upper surface, and approaching at its outer part, but not involving, the ascending white fibres of the crus. No secondary degeneration was found in the cord.

PROGNOSIS.—This is almost always unfavorable. In some cases the inco-ordination decreases and the spasm becomes less violent, but it seldom disappears altogether. One of Gowers's cases was benefited by treatment, and two of those related by Hammond were relieved.

TREATMENT.—Many remedies have been given without marked benefit. In Gowers's case there is no doubt that the decided improvement which took place was due to galvanism. The treatment lasted three months, and a descending galvanic current was used. The positive pole was put upon the nucha, and the negative on the over-acting muscles and on the hand and foot. One of Hammond's cases, as related above, was apparently cured by stretching the median nerve. A prolonged course of galvanism and some alterative, like mercury or chloride of gold and sodium, would seem to offer the best prospect of benefit.

LOCAL CONVULSIVE DISORDERS.

By ALLAN McLANE HAMILTON, M. D.

Thomsen's Disease.

SYNONYMS.—Rigidité musculaire avec impuissance de la volonté; Rigidité et hypertrophie musculaire; Myotomé congenitale.

In the year 1876, Thomsen,¹ the medical officer of Kappeln, described a curious form of nervous disease which affected several members of his own family, himself included. It consisted of a tendency to cramp and limited spasm when a voluntary act was attempted, and a seeming and sudden loss of power. This condition disappeared after the performance of the act and its repetition. An attempt at walking would be attended by spastic rigidity of the flexor muscles of the lower extremities, by flexion of the thighs and legs at an angle of 120°, so that the patient often fell forward upon his knees. An attempt to arise from the chair was attended by the same difficulty, the person becoming utterly helpless. The arms and legs were most frequently affected, the trunk-muscles being usually exempt. In some cases the muscles supplied by cranial nerves were the seat of spasm, so that the patient could not close his mouth nor shut his eyes. Westphal, Erb, Peters, Schönfeld, Engel, and others have reported about eight cases in all, and in addition to the symptoms above referred to it was found that mental excitement and cold chiefly precipitated the seizure. The sphincters were never affected, and the general nervous functions were not impaired. The patients talked stiffly, and this was probably due to a spasmodic affection of the lips, tongue, and other articulating organs. The tendinous reflexes were normal, but irritation of the soles produced a peculiar cramp of the leg-flexors and bending of the knees. There is a species of muscular increase which resembles pseudo-hypertrophic paralysis.

The malady seems to be of an hereditary nature, if we are to judge by Thomsen's cases. It begins early in life, and does not materially shorten the same. I have seen one case, a young child, which presented the main symptoms of, and was first mistaken for, pseudo-hypertrophic paralysis.

Westphal regards the affection as an "anomaly of muscular tonus;" others have shed no light upon its pathology.

I believe the condition to be an occasional feature of certain organic disorders, notably posterior spinal sclerosis, and there is a variety of paralysis agitans where there is no tremor which presents all the symptoms. The very rare nature of the malady and its peculiar expres-

¹ *Berliner klin. Woch.*, Mar. 12, 1883.

sion render diagnosis easy. It possibly may be mistaken for pseudohypertrophic paralysis in young subjects, but in this latter disease we find electrical change in the muscles, and an absence of the tendon reflex. An examination of the enlarged muscles will not reveal fatty increase.

Painless Facial Spasm.

There is a form of spasm of the muscles supplied by the facial nerves which differs from ordinary *tic douloureux* by the fact that there is no pain in the former. The trouble may be one of a very limited nature, consisting of the involvement of a few fibres, or of limited groups of muscles, or of all the muscles of the side of the face. I never have seen a case of double spasm, though such undoubtedly exist.

The nature of the paroxysm is cumulative, and, as a rule, the attack increases until it reaches an acme of intensity, then quite suddenly ceases. It often begins by a slight drawing of the corner of the mouth, the levator anguli oris and other muscles in the neighborhood being the seat of chronic spasms. This limited spasmodic action is followed by further facial contractions. The orbicularis palpebrarum is often the sole seat of the convulsive movement, and this is common in excessive smokers.

As a rule, the trouble is peripheral and due to some reflex cause, such as cold, injury, bad teeth, which produces reflected irritation through the branches of the fifth nerve, or in rare cases it may be central or due to some bony or other pressure upon the nerve in its passage through the skull. In a recent case the trouble was of evident central origin, and I obtained a history of lightning pains in the lower extremities, some inco-ordination of muscles in both upper and lower extremities, and some paresis of the facial muscles. In this case the spasms involved all the muscles of the right side of the face, and recurred every few minutes. They had first appeared five or six years before I saw the patient, and had gained in frequency from two or three daily until within the past four months they occurred, as I have said, every few minutes. The other symptoms were of insignificant character compared to the spasms.

Of the large number of cases I have seen, many impressed me as being the result of a simple bad habit, yet moral or other measures did not avail much.

It is important to diagnose certain unusual forms of facial spasm from the *petit mal* of epilepsy, and careful observation will detect a transitory loss of consciousness in the latter. It is equally important to find a cause if any exists, and a careful examination of the state of the teeth, the integrity of vision, and the possible existence of aural disease should be made in all cases. In some cases over-use of the eyes, which may be defective in their power of accommodation, may precipitate blepharospasm. In other cases the act of masticating hard substances or taking very hot or cold fluids into the mouth may give rise to the spasm.

Hyoscyamine in repeated doses of from $\frac{1}{200}$ to $\frac{1}{25}$ grain of Merck's crystals does more in the way of relieving the spasms than any other drug of which I know. If this does no good, gelsemium cautiously used is often of great service. Local galvanic applications with currents of great intensity will form a valuable adjuvant. So far, I have never tried

nerve-section or stretching in these cases, but recommend them as a dernier ressort.

Torticollis.

SYNONYMS.—Wry neck, Rheumatismus colli, Obstipite, Cephaloxia.

Wry neck or torticollis consists essentially of a spasm of the sternocleido-mastoideus, though other muscles are nearly always involved: the result is a peculiar and striking distortion which is quite familiar. It consists in the drawing downward and backward of the head on the affected side, while the chin is pointed forward and upward to the other. The disease is presented in several forms. It may be a temporary disorder as the result of a rheumatic condition, disappearing rapidly, or occurs as an hysterical affection, or it may be a chronic and intractable nervous disease. We must also consider it from the standpoint of the form of distorted motility. In some cases there is simple tonic contraction, which may eventually result in tense contracture, shrinking, and tendinous hardness; and in others the attention of the physician is attracted by a species of tremor and agitation. Unlike the tremor of sclerosis, this is uninfluenced by the attempts of control upon the part of the patient, but is aggravated by fatigue and excitement. It rarely happens that both muscles are affected so that the head is drawn backward. Most of the cases are single, chronic, and progressive, and, though very slow in the onward march, are usually beyond the reach of remedies. The patient becomes greatly annoyed by his infirmity, and seeks every measure to overcome his unfortunate deformity. He commonly tries to hold his head or chin, pressing the latter downward, or, holding his cane against his head upon the dependent side, strives to keep it up. As a result, there is a sagging or drooping of the affected side of the body, so that one shoulder is lower than the other.

The disease, as a rule, begins in adult life, yet there are many young cases.¹ Wilks calls attention to the fact that in these latter there is apt to be some facial asymmetry on the contracted side. One side of the head is smaller than the other, and one eye seems to be lower.

Most of the cases I have seen have been men, though I have met with many hysterical examples in young girls. The double torticollis (Newnham's salaam convulsion) usually affects children, and it is the rule to find associated strabismus and intellectual disturbance. In the adult cases there has usually been a history of hereditary neurotic influence and overwork.

Electrically, we find a susceptibility to both currents, and the reaction of degeneration may be detected in the affected muscles in old cases. The opposing muscles are usually the seat of diminished electrical excitability.

Torticollis may be due to peripheral or deep causes. Cold, reflex irritation, forced and uncomfortable positions, are to be mentioned among the former, and intracranial or vertebral disease as examples of the latter. The pathological explanation lies in a disorder of the motor fibres of the spinal accessory nerve. Any affection of the external branch will result in the condition above described.

¹ *Diseases of the Nervous System*, p. 454.

In young cases the PROGNOSIS is good as a rule, though this is by no means invariably so, for sometimes the special symptoms are but forerunners of others of a more grave character. Hysterical torticollis is often instantly, or at least very readily, cured by electro-therapeutics and cauterization. A well-established adult case is almost hopeless and resists all ordinary treatment.

Many forms of TREATMENT have been recommended from time to time, and such drugs as the bromides, chloroform, conium, and hyoscyamine are suggested. The latter I believe to be the most serviceable remedy. Electricity has done good in either form, and vigorous faradization with the electric brush is earnestly recommended in hysterical, rheumatic, or functional cases. Some years ago I devised a method which in a number of cases has been of great service. I allude to the combined and simultaneous use of the galvanic and induced currents. A double electrode is applied to the back of the neck. This contains the anodal pole of the galvanic current and the cathodal of the faradic. The two other poles are placed—one, the galvanic cathode, over the origin of the affected muscle, the induced anodal pole over the weakened muscle which is not in spasm. I suppose in old cases the most valuable treatment is that of a surgical nature. I have twice seen the spinal accessory excised with the result of a complete cure; and I think this is the only sure measure. H. B. Sands of this city has performed the operation quite successfully in other instances. Care should be taken not to operate in cases presenting other symptoms which suggest the remotest suspicion of organic cerebral disease, and the existence of unilaterally increased tendinous reflexes or tremor should be carefully looked for as contraindications.

Braces and apparatus are often worse than useless, increasing not only the patient's discomfort, but aggravating the malady.

Eclampsia.

(*Εκλαμψία* and *λαμπω*, "I shine," brilliancy, flashes of light from the eyes.—Dunglison.)

DEFINITION.—A term used to express certain irregular convulsive attacks, as a rule due to eccentric irritation, uræmic poisoning, or like causes, and chiefly used in connection with the convulsions of infants.

This term has gradually been dropped in scientific medical literature, and many authors think it useless, believing the condition to be usually epileptoid. Nothnagel,¹ who is more liberal than many other clinicians, says: "What is there now remaining of what was formerly eclampsia? Are we altogether justified in still retaining the name? We believe so, and are of the opinion that the title eclampsia should be reserved as the name of an independent affection, which, it is true, can at present be defined only by its clinical symptoms. We propose that the designation eclampsia should be made use of for those cases of epileptiform spasms which, independent of positive organic diseases, present themselves as an independent acute malady, and in which, so far as our present knowledge allows us to judge, the same processes arise generally in the way of reflex

¹ *Cyclopædia of the Practice of Med.*, Von Ziemssen, Am. ed., vol. xiv. pp. 301, 302.

excitements, and the same mechanism in the establishment of the paroxysms comes into play, as in the epileptic seizure itself."

If any distinction at all be made, it should be one founded upon the fact that epilepsy itself is usually an organic disease, or, more precisely, a disease which when established is dependent upon some disorganization, while eclampsia is used to express those seizures of a purely functional nature.

By far the greater number of eclamptic seizures are found among young children. There is no uniformity in their expression or return. Any eccentric irritation is apt to precipitate one or more attacks, and those forms of irritation dependent upon sensory disturbances of the mucous membrane are commonly present. The convulsions of teething belong to this class, as well as those in which gastric disorder plays a part; and in the first instance the cutting of the large teeth, and in the latter the presence of indigestion with diarrhœa, are quite commonly associated with the convulsion.

The high degree of irritability of the nervous system of children renders them peculiarly susceptible to causes which in after years would effect little or no disturbance; and this is especially true before the fifth year. West and Reynolds are of the opinion that convulsions occur in children as delirium in adults; in other words, they are the most common expression of neurotic instability.

Infantile convulsions are usually general, and neuro-spasms are not common, except when they are dependent upon neoplasm, ventricular dilatation, or local meningitis. It evidently takes very limited peripheral excitement to precipitate a general convulsion in the child, and a familiar example is the disturbance which may involve the peripheral branches of the fifth nerve in difficult dentition.

Eclamptic seizures occur at any time, and may be very slight: a trifling twitching may be all, or, on the other hand, the attack may consist of violent opisthotonos. There is great difficulty, of course, in getting anything from a young child as to its feelings before an attack, and I hardly think we are authorized in saying that there is any aura or ascertainable precursor. The history of a previous nervous state is, however, usually ascertainable, which is expressed by crying fits, peevishness, and great restlessness. Sometimes there is a disposition to sleep which almost amounts to stupor. The behavior of a child is often likened to that which marks the commencement of acute tubercular meningitis—night-terrors, grinding of the teeth, and flushing of the face. The first convulsions may be only partial, but in a short time their character becomes general, and they become exceedingly violent, and are sometimes fatal. The clinical features of an eclamptic seizure may in every respect resemble one of epilepsy, making allowance for the age of our patient.

The stage of pallor is perhaps more extended in the child.

Handfield Jones speaks of a form of eclampsia of hyperemic causation in association with certain exanthemata. In children convalescing from scarlatina he observed the development of attacks which were relieved by carotid pressure and bleeding in subjects who presented anasarca and other indications of renal disease.

We are familiar enough with the convulsions of puerperal women, which, as a rule, though not always, are presented by subjects whose

urine is albuminous. It can sometimes distinctly be traced to what must be regarded as uterine excitement. Just as chorea is often a feature of the pregnant state, so may convulsive seizures arise. The peculiarities of the epilepsy of pregnancy will, however, be elsewhere considered.

I shall purposely refrain from the consideration of those forms of symptomatic infantile convulsions which mark the occurrence of cerebral accidents or grave disease.

EPILEPSY.

By ALLAN McLANE HAMILTON, M. D.

SYNONYMS.—Epilepsia; l'Épilepsie (*Fr.*); Fallsücht (*Ger.*); Epilessia (*Ital.*); Epilepsin fallendsot (*Scand.*); Falling sickness; Fainting sickness.

DEFINITION.—According to the most recent authorities, an epileptic attack is nothing more nor less than a discharge of nervous energy from an overexcited, or what may be called a dynamo-pregnant nerve-centre, or collection of centres, and the predominance of motor or sensory phenomena determines the extent and order of the parts involved. As a rule, an epileptic paroxysm is but a symptomatic expression of a complex derangement, and it is best to formulate our nomenclature with the idea, in the first place, of location; in the second, with reference to the prominence of motor or sensory expressions; and, finally, with regard to etiology.

HISTORY.—There is probably no nervous disease which has been more extensively written upon (even in ancient times) than that under consideration. We find references to it as early as the tenth century, when it figured in the text of Avicennes. Hippocrates called it *ιερόν νοσεμα*, or sacred malady, and *πάθος παιδῶν*, or malady of children, believing that the attacks had their origin always in early infancy and never later. Plato and Aretæus advanced the theory that the disease sprang from a thirst for gold, and equally absurd and unreasonable explanations are found in the writings of the fathers of medicine. The older French writers were diligent investigators, but with them prevailed the tendency to explain the origin of the disease by mysticism, and among many it was supposed to bear some connection with the coming of St. John. The popular humoral theory of the malady originated by Mercurialis was afterward opposed by Avernhoes and Fernel, but even to this day it has devoted adherents. Bouchet and Causauvicih maintained that the disease was inflammatory—a view that was vigorously combated by Bouillaud and Delasiauve. The theory of Broussais—which was and is the basis of the conclusions of modern investigators—is that it is dependent upon cerebral irritation. It is hardly necessary to refer to the many untenable and curious attempts that have been made to explain the pathology of the malady: suffice it to say that many of them were as extravagant as that of Vepfer, who considered the pineal gland to be the *locus morbi* of the affection—a conclusion in which Descartes coincided. Marshall Hall was the first writer to advance the theory of reflex irritation,

believing that gastro-enteric or uterine irritation acted upon the brain. In later years Schroeder Van der Kolk, Reynolds, and others have written quite fully upon the part played by the medulla, while recently numerous French and German writers—among them Bourneville, Meynert, Sommers, and Tagges—have attached much importance to the discovery of a sclerosis of parts lying at the floor of the lateral ventricles.

Perhaps our knowledge of epilepsy has received its greatest impetus from the elaborate and exact researches of Hughlings-Jackson; and his observations, taken in connection with the recent work of the numerous students of localization, open up a new field of research, and, as matters stand, the future study of epilepsy must be fruitful in the extreme.

DIVISION.—It has been the custom to divide the epilepsies into *epilepsia gravior* and *epilepsia mitior*, the *haut mal* and *petit mal* of the French. These terms are in one way misleading, and only define differences in degree. The terms general and limited would much more properly express the forms of attack, and I shall use them as far as possible in the present article. A general epilepsy is one that corresponds with *haut mal*, in which there is an extensive convulsion, absolute loss of consciousness, and perversion of a widespread character. Limited epilepsy includes those forms in which there is a convulsion confined to a small group of muscles, and in which loss of consciousness plays an unimportant part. Under this latter head belongs the form known as *petit mal* and those *monospasms* which depend upon a cortical irritative lesion. There are other divisions which partake of the nature of one or the other, and are unilateral and dependent upon the destructive discharge of a motor centre. Under this head may be placed the *epilepsie partielle* of the French or the *hemi-epilepsy* or *Jacksonian epilepsy* of the English. There are also irregular or aborted attacks—the so-called *masked epilepsy*—and lastly the sensory varieties.

ETIOLOGY.—It cannot be denied that heredity plays the most important part in the genesis of epilepsy. Nearly one-half of my own cases when carefully investigated were clearly traceable to some inherited predisposition. Insanity, epilepsy, and phthisis in ancestral history stamp their constitutional imprint upon the unfortunate descendant, and the history of ten cases from my notebook (see Table) will show the extent of saturation that may exist in paternal or maternal branches and the evolution of the disease in male and female subjects. The statistics of other writers, though not showing quite so large a proportion of cases with hereditary history as my own, are quite significant. Gowers found that in "1218 cases, 429, or 35 per cent., presented evidence of neurotic inheritance." Echeverria estimated the proportion of hereditary cases at 28 per cent., while Reynolds fixes it at 31 per cent. Of 980 cases, the notes of which I have examined, many of whom have been under my personal care, 435 presented a family history of insanity, phthisis, epilepsy, cerebral apoplexy, tumor, or some lesser neurosis. So far as the history of hereditary influence is known, it appears that females are more apt to present this form of epilepsy than males, and, according to Gowers's as well as my own investigations, the transmission comes from the mother's side more frequently than the other. So far as my own inquiries have gone, I find insanity more often among the progenitors of the epileptic than any other nervous disease, and in many cases phthisis. I am

Hereditary in Ten Cases of Idiopathic Epilepsy, with Existing Disease or Cause of Death.

| Sex. | Paternal Ancestry. | | | Maternal Ancestry. | | | Brothers. | Sisters. | Remarks. |
|--|---|---------------|-----------|--------------------|---------------|-----------|--|--|---|
| | Father. | Grand-father. | Uncles. | Father. | Grand-father. | Aunts. | | | |
| I. Died Insane. | Struck; probably Insane. | Insane. | Insane. | Insane. | Insane. | Insane. | One a dipsomaniac; one epileptic; one in good health. | One epileptic. | Abi-tory of criminal proclivities. |
| M. Alive. | Cerebral hemorrhages. | Insane. | Insane. | Insane. | Insane. | Insane. | One brother has infantile paralysis. | Two sisters died of organic disease of the brain, one of cerebri-spinal sclerosis. | Peculiar granum. |
| I. Alive in third stage of post-sp. sclerosis. | Phthisis. | Phthisis. | Phthisis. | Phthisis. | Phthisis. | Phthisis. | Younger brother died of tubercular meningitis. | | |
| M. Died of phthisis. | Not known. | Phthisis. | Phthisis. | Phthisis. | Phthisis. | Phthisis. | No brothers. | No sisters. | Peculiar granum. |
| M. (congestive hemorrhage). | Insane. | Insane. | Insane. | Insane. | Insane. | Insane. | One died of phthisis; one hemiplegic. | Eight brothers and sisters. | One died of epilepsy and cerebral tumor was found; one paralyzed. |

| M. A congenital drunkard. | Died of encephalitis and softening at 75. | Insane. | Insane. | Insane. | Insane. | Insane. | One brother died of secondary tubercular meningitis, the other in an asylum. | | Child of this parent was choreic. |
| M. Phthisis. | Eccentric. | Phthisis. | Phthisis. | Phthisis. | Phthisis. | Phthisis. | | | Criminal proclivities. |
| M. A dipsomaniac and eccentric person. | Insane. | Insane. | Insane. | Insane. | Insane. | Insane. | Several brothers afflicted. | No sisters. | Criminal proclivities. |
| M. Most eccentric; a somnambulist. | Insane. | Insane. | Insane. | Insane. | Insane. | Insane. | No brothers. | No sisters. | Criminal proclivities. |

inclined, therefore, to give greater weight to this relationship than Nothnagel and others. Austie, Bastian, Savage, and other careful clinicians have pointed out not only the close connection between phthisis and epilepsy, but between the former disease and migraine; and no one who has seen much of epilepsy can fail to be impressed with the frequent association of migraine with the more serious convulsive affection of which it is quite often the precursor. Perhaps the fact that phthisis was found so often—in 230 of my 980 cases—may be due to the fact that many of the patients were of the lower classes and among the Irish, who in this country are so frequently phthisical.

In many idiopathic cases we find vices of cranial conformation, bodily asymmetry, and a history of early congenital syphilis. Laségue lays great stress upon cranial malformation, and goes so far as to say that all epilepsies not dependent upon some osseous trouble, either developmental or traumatic, are not epilepsies at all. Such epilepsy, which owes its origin to cranial asymmetry, rarely develops after the eighteenth year. The head is most often dolichocephalic or brachycephalic, and there is facial asymmetry. Laségue concludes that all the convulsions are identical; that it is not hereditary; that the attacks are always matutinal. It seems to me that Laségue's conclusions in regard to the non-existence of epilepsies from other causes are rather too arbitrary in view of the large amount of evidence to the contrary. In others, a very few, we find an apparent history of heredity explained by forceps-pressure during delivery.

So far as age and sex are concerned, and their predisposing influence, we find that by far the greatest number of cases begin before the twentieth year. This is the experience of Gowers, of Hammond, and of many others. Of my own 980 collected cases in which the beginning of the disease was known, there were—

| | Females. | Males. | Total. |
|-----------------------------|----------|--------|--------|
| Under 10 | 103 | 95 | 198 |
| Between 10 and 20 | 171 | 97 | 268 |
| “ 20 and 30 | 145 | 92 | 237 |
| “ 30 and 50 | 81 | 136 | 217 |
| Over 50 | 11 | 49 | 60 |
| | 511 | 469 | 980 |

Of 1288 cases collected by nine French authorities, in 486, or over one-third, the disease began between the tenth and twentieth years. In Gowers's 1450 cases we find the following showing:

| Cases. | Cases. |
|-----------------------------|----------------------------|
| Under 10 422 | From 40 to 49 31 |
| From 10 to 19 665 | “ 50 to 59 16 |
| “ 20 to 29 224 | “ 60 to 69 4 |
| “ 30 to 39 87 | “ 70 to 79 1 |

In 29 per cent. of these cases the disease therefore began before the tenth year.

As to sex, it appears that females are much more subject to the disease than males, but this is not true at any age. Epileptics under ten are more apt to be girls, but the proportion is nearly equal: between ten and twenty the proportion of females is undeniably greater. In adult cases we find that pure epilepsy (excluding hysteria) is much more often a disease of males than females.

In the hereditary form the disease in the great proportion of cases begins before the twentieth year; and, so far as my experience goes, this kind of the disease makes its appearance at a very early age. The part played by particular predisposing influences appears to be well defined. The children of syphilitic parents develop the disease at a more advanced age than when alcoholism is found to exist. In adult males, when the disease develops late in life, it is almost always possible to find syphilitic or coarse brain diseases, while among women the history of antecedent migraine or menstrual derangement is nearly always present, and the convulsions in a very large number of instances have a hysteroid character.

The exciting CAUSES of the disease are quite numerous. Traumatism is a frequent and important etiological factor, and the head-injuries may be recent or remote. It is quite common to find old fractures, with depressions which have existed for years without any seeming bad effects, suddenly lighting up convulsions under the influence of some new excitement. Under such circumstances the depressed bone is quite apt to give rise to symptoms suggestive of meningeal irritation and inflammation, so that the diagnosis is comparatively easy. Several observers have called attention to epilepsy which has been undoubtedly due to cicatrices not only of the scalp, but elsewhere, and these may or not be found in association with osseous lesions. The literature of the subject is replete with curious cases which go to show that epilepsy may occur from a few days to many years—even twenty—after the initial head-injury. Unsuspected cortical pressure, the inner table being alone depressed, is common; in fact, the cases in which the most serious mischief is done seem to be those where the only external evidence of violence is the contused scalp. As a consequence of such injury we may have exostoses developed.

The influence of syphilis in the production of epilepsy is one of very great importance. Not only has specific epilepsy characteristics of its own, but its origin may be distinctly traced to syphilitic infection. Cases dependent upon gross cerebral disease, such as meningitis or gumma, are excluded from consideration, but it is conceded by all syphilographers that an epilepsy may mark the second stage of the disorder, and its pathological dependence is probably a simple vascular disturbance which cannot be determined after death. So-called specific epilepsy may be congenital.

Orwin¹ mentions as a cause the influence of prolonged lactation. In several cases I have seen a metrorrhagia, or a loss of blood from hemorrhoids has been followed by a readily curable epilepsy.

As eccentric irritating causes may be mentioned intestinal worms, but I am convinced that it is too often the fashion to ascribe convulsions in children to intestinal parasites: in very young children, however, there are frequent examples of the disease in which the attacks are precipitated by worms. The fits are usually very severe, and are not regular in their appearance, occurring at night-time more often than during the day, and, though they usually disappear when the bowels are cleared of their unpleasant occupants, may recur when once initiated, even though anthelmintics of the most powerful kind are employed. Gall-stones are mentioned by Ross as an eccentric cause of the disease, but I have never witnessed a case of this nature.

¹ *Prov. Med. and Surg. Journal*, London, 1862, v. 48.

Sudden terror, fright of all kinds, morbid example, and other psychic causes are detailed, and undoubtedly all have more or less influence. Hysteroid attacks are notably precipitated by these mental causes, and all forms of the disease are greatly modified by abnormal exercise of the mind.

A number of writers, among them Baly¹ and Booth,² have called attention to cases of the disease dependent upon carious teeth. I have seen but one such case, where a wisdom tooth produced so much violent inflammatory action that middle-ear disease followed, and with it subsequent extension to the brain took place.

In rare cases the administration of anæsthetics is followed by epilepsy, and Gowers alludes to a case in which convulsions were due to the inhalation of nitrous oxide gas.

Concussion of the brain as the result of railroad injury or falls may give rise to a progressive epilepsy which is usually of serious character.

Reflex causes play a prominent part in many instances, though I am inclined to think that their importance has been greatly exaggerated. This is especially true of so-called uterine epilepsy. It cannot be doubted that difficult menstruation, ovarian neuralgia, etc. are found in connection with epilepsy, but whether as a cause or effect it is not always possible to say. The fact that in some women we find accès at periods identical with menstruation would point to a very close relationship. Carstens³ reports a case due undoubtedly to stenosis of the cervix; Cohen,⁴ an example in which there was a uterine fibroid; and others have spoken of erosion of the cervix, etc. as possible explanation of the seizure.

The toxic forms of epilepsy hardly need discussion in this article. Metallic poisoning, which gives rise to a veritable plumbic encephalopathy, is rather the cause of a symptomatic than generic epilepsy. Curious cases of epilepsies which have followed the use of oil of tansy (Mitchell⁵), ergot, absinthe (Magnan⁶), and various drugs show that occasionally their mode of origin may explain the convulsive seizure. Alcoholic epilepsy I do not regard as being the rare affection some authors consider it. In cases of prolonged saturation, where perhaps there are no other symptoms of chronic alcoholism, I have found it perhaps associated with the trance state (cataleptoid) or appearing in the psychic form.

In old persons I have found gout to have an undoubted influence in producing the disease, there being a spasm of the cerebral vessels which usually betokens a condition of uric-acid saturation. In these cases the painful symptoms were not decided. Such epilepsies have quite often preceded serious evidence of arterial degeneration.

Malarial epilepsy is rare: Jacobi⁷ reports a case and Payne⁸ another. A young man was brought to me last year who had lived for many years in a part of Pennsylvania which was exceedingly malarious. His attacks, which were more or less periodic, were violent, and his convulsions were

general and attended by very great preliminary rise of temperature and intense congestion of the face and head. The patient was unusually somnolent, and between the paroxysms frequently suffered from facial neuralgia. The influences of change of habitation and quinine determined the correctness of my diagnosis.

Day¹ and Kerr² have both ascribed epilepsies seen by them to hepatic congestion.

The important etiological relation of the exanthemata to epilepsy has been the subject of much attention. The books are full of cases which owe their origin not only to scarlet fever and measles, but to whooping cough, diphtheria, and the various zymotic fevers. In 35 cases tabulated by Gowers³ (p. 28) no less than 19 were due to scarlet fever, while the first fit followed measles in 9 cases. So far as my individual experience goes, I have in 23 cases found epilepsy to be the result of scarlet fever, and this form of the disease was often associated with other manifestations of coarse brain trouble. Cerebro-spinal meningitis was the undoubted cause of epilepsy in 6 cases I examined. It is probable that just as smallpox acts upon the nervous centres, so does scarlet fever, and I agree with Gowers that the convulsions that may begin during or just after the fever are not always due to uræmia. Bright's disease may give rise to an epilepsy, but this can hardly be regarded as a distinct affection.

There are many cases, especially in adults, which grow out of a prolonged depletion of the brain—a continued cerebral anæmia. Among these cases are some which depend upon pressure upon the great vessels of the neck, and some due to debilitating disease of a general character. Schulz⁴ has seen a case which followed compression of the jugular vein, and enlarged cervical glands have in other cases acted as mechanical agents. Hammond alludes to the influence of prolonged general anæmia in the production of epilepsy.

While I do not place much reliance on the claims that have been made regarding the frequent dependence of the disease upon preputial irritation, or that it may arise from phymosis or urethral stricture, it cannot be denied that some cases have originated in difficulties of the kind, and especially the former. Simmons⁵ reports a case of attachment of the prepuce to the glans in which a cure followed separation. Disease of the testicles in certain cases plays a part in its genesis, and Liégey⁶ details an epilepsy clearly due to testicular pressure. Some years ago I saw a case in which the pressure of an improperly applied truss, I am now convinced, had much to do with the development of the convulsions. The alleged sexual causes are many, and some of them are very doubtful. A fanciful continental writer, Montmeja,⁷ believes that sodomy explained the appearance of the disease in one of his patients.

The existence of vesical calculi as an exciting cause cannot be disregarded, and, while rare, the observations of Duncan,⁸ Muscroft,⁹ and one

or two others have shown that the removal of a stone was followed by a cure of the epilepsy.

Masturbation is a popular etiological factor. I really do not believe, even in face of the numerous alleged cases that have been recorded, that the habit of self-abuse often results in genuine epilepsy. So far as my experience goes, onanism is practised by epileptics as well as by healthy boys, and when indulged in to excess is due to the congenital moral deficiency which is so common, especially in hereditary cases. In rare examples the frequently-repeated act may give rise to a form of the disease of the nature of *petit mal*.

Gastric disorders have attracted much attention, especially from Paget, who speaks of a gastric epilepsy and reports cases. While I do not believe in the sole etiological influence of digestive derangement, I have too often witnessed examples in which disorders of this kind markedly influenced the precipitation of attacks and the duration of the disorder.

Occasional cases of peripheral origin have been from time to time presented, and go to support in some measure the pathological views of Brown-Séquard. Among observers who have brought forward cases besides those referred to on a previous page are Lande,¹ who reported a case of epilepsy dependent upon injury of the right median nerve, and Short,² in whose case a neuroma explained the cause of the convulsions. Billroth,³ Garnier,⁴ Brown-Séquard,⁵ and Raymond⁶ have brought forward cases where injury of the sciatic nerve was the origin of the trouble, and in more than one instance a cure was effected by excision. It seems strange that a bone dislocation should have anything to do with the genesis of epilepsy, yet in one case reported a severe dislocation at the shoulder-joint explained the appearance of the attacks, and reduction was speedily followed by cure.

I have seen several cases where disease of the internal ear or injury of the temporal bone gave rise to the most obstinate and violent epilepsies. Westmoreland⁷ and others report such cases, but more often the epilepsy is only symptomatic of pachymeningitis or abscess. Some years ago I presented⁸ a case of genuine epilepsy in which the seizure was produced at will by irritating the meatus auditorius. By simply blowing into the ear the same effect would be produced. Since then Blake and others have related examples. Quite lately a writer in *Brain* has collected other cases of this species of auditory epilepsy. A year or so since I examined a patient in whom not only hemi-epilepsy, but other unilateral symptoms, followed erosion of a large part of the mastoid and petrous portion of the temporal bone as the result of a bullet wound.

The influence of climate and varying barometric pressure has been considered by Delasiauve. His conclusion was that the attacks were much more common during the season of the year when the prevailing winds were from the north-west, north, or south-west.

PRODROMATA.—There are various minor disturbances of sensation and motion which may not amount to the dignity of an epileptic attack. These may be so fugacious as to escape the attention of the persons in whose company the patient may happen to be, or he himself may be unaware of any disordered state of feeling. They may precede a severe paroxysm, when they are known as warnings or *auræ*. The term *aura* was originally applied to the familiar premonitory sensation which is so often likened by the subject to the blowing of wind over the skin, from whence it receives its name, but it has come to be applied to all primary indications of a fit. Such *auræ* may be sensory or motor—in the preponderance of cases the former, for motor precursors are quite rare, and when they occur are most likely to be but one stage, though a slight one, of the convulsion itself. There is no general rule about the occurrence of an *aura*, but, so far as my experience goes, there is great constancy in the character of the warning in each particular case. The sensory disturbance may vary from a vague feeling of confusion to a well-marked sensation. In many instances the patient speaks of an indescribable mental disturbance, which may precede the attack and last anywhere from a few minutes to several hours. This confusional state or psychical *aura* is most protean in its expression. It may simply be a heavy feeling, a feeling of tension, a sleepy feeling; a restlessness which is manifested by the patient changing his position frequently or wandering forth into the streets; an irritability of temper which often lasts twenty-four hours or more, and during the display of which he rebukes those who may be solicitous about him, or wantonly destroys articles of furniture, or vents his spleen upon inoffensive persons. I have had epileptic children under my charge who were wont to bite their little brothers and sisters or their nurses. A feeling of terror sometimes precedes the attack, and very often there is a sense of impending danger which has no basis whatever, and with it is associated a depth of depression which is very painful. In other cases the patient manifests a strange exhilaration, which may precede the occurrence of the attack for a period of from one or two hours to two or three days; and this is made manifest by great loquacity and a lively play of spirits. It is not rare to find errors in the speech as indications of an approaching attack. A minor degree of aphasia, slowness of speech, or anarthria betrays occasionally the preparatory state which is the precursor of a severe convulsion. By far the most common warnings, however, consist of disorders of the special senses, and generally these are visual. From an inspection of my notes I find that the patients saw colored lights, rings of fire, bright objects, dark spots, luminous clouds, a flood of light, sparks, stars, bright balls, lights which approached them, lights which receded, fireworks, and all became dark. While many were unable to define the color perceived, I found among those who were positive that red was the color most frequently seen, while blue came next; and this is a conclusion which I believe is accepted by Jackson and others who have analyzed their cases.

Hemiopia and diplopia in rare cases precede the major attacks, and are sometimes associated with distal pain and anæsthesia and with supra-orbital pain as well.¹ Among these ocular warnings we find constriction of the visual field to be often present, especially in cases where there is a

¹ See Sensory Epilepsy.

history of migraine. Vague disorders of hearing, which may even amount to the dignity of hallucination, are complained of by some persons. There may be simply roaring in the ears or a sound of bells, and in one instance my patient declared that he heard whisperings at the time of the seizure. Some patients smell smoke or other foul odors, and in exceptional instances the odor of some particular flower or of some aromatic substance, such as camphor, turpentine, or tar, is perceived by the epileptic; and these are probably psychical.¹ Sometimes there is a feeling of great suffocation, constriction of the chest or of the throat, palpitation, or vertigo.

There are disorders of cutaneous sensation of great diversity of character, but those auræ which are of the most constant occurrence are the epigastric, which consist of a vague sensation starting below the sternum and ascending, its arrival at the throat being coincident with the commencement of the fit, and the patient very often likens its culmination to the violent grasp of a strong hand. So, too, we find crawling sensations starting in the extremities and running up to the trunk. These have been compared to the contact of insects in motion or to the blowing of wind over the surface. There may be tingling in one or two fingers or the whole hand, and such sensations may be unilateral or bilateral. It is quite common for the sensory warning to begin in the hand and foot of one side and to run up to the knee and elbow. Sometimes the tongue becomes hyperæsthetic, and I have frequently found that the gums became exquisitely tender just before the attack. According to Gowers, 17 per cent. of his cases began with unilateral peripheral auræ, but I think this is too small a proportion, for, so far as I have observed, at least 30 per cent. of all my cases in which any auræ at all could be ascertained presented the history of a one-sided warning, beginning most often in the right hand. Gowers says that in three-fourths of his cases in which the attack began in the hand consciousness was lost before the seizure extended beyond the arm, while in the others it extended much farther before the actual fit was precipitated. In Gowers's cases he rarely found that unilateral auræ were associated with other warnings; and his experience, which is like my own, goes to prove that unilateral sensory auræ and one-sided initial motor expressions go together, and very often indicate gross organic disease. In some cases there may be for several days a decided unilateral or general muscular weakness or recurring chronic spasms which may be frequently repeated. In aborted or irregular attacks there are also peculiar motor symptoms, to which reference will be made later on.

In two or three patients I have found that the attack was immediately preceded by a profuse discharge of saliva, and in one case the patient had frequently bleeding from the nose. Several authors have called attention to certain local vaso-motor disturbances which are expressed by limited patches of cutaneous hyperæmia or anæmia, so that the fingers—or, in fact, the whole hand—may either be swollen and of a dusky-red color, or, contrariwise, there may be blanching and an apparent diminution in size.

Sometimes the patient immediately before the attack makes more or less automatic movements, pressing his hands to his head, clasping his breast,

¹ For curious examples of this kind consult Sir Charles Bell's *Nervous System of the Human Body*.

or clutching at some imaginary object, and after this he loses consciousness and falls to the ground. In some irregular cases the patient runs aimlessly for some distance or describes a circle, and after a variable time, which rarely exceeds a minute or two, the actual fit begins. Here are two examples :

Case I.—Boy aged fifteen, has been subject to somnambulism ; attacks began two years ago. He frequently when sitting at table rises suddenly, and runs either around the room or out into the street if possible. In thirty seconds or so he falls to the ground in a convulsion. Always falls backward in opisthotonos.

Case II.—Man aged thirty-four. Attacks always begin by stage of violent temper. While unconscious he runs about office, striking all who try to restrain him ; finally falls to the floor. Convulsions, when they occur, are always severe. Sometimes running attack is the sole feature.

This disposition to run is no less remarkable than another queer prodroma I have seen in several patients, who began to take off their clothing when first seized, no matter where they were or under what circumstances. This is not, as has been suggested, the remains of a half-formed idea that they must seek their beds because of their impending trouble, but it is a much less complex mental act, and the several patients I have seen were fully unconscious when they did this, and were in places where there was no bed within reach. Equally curious mental precursors of the attack have come to my notice, and these I will detail subsequently.

SYMPTOMATOLOGY.—The Light Attack.—The epileptic attack may, as I have said, be scarcely perceptible to those about the patient, or may consist simply of a momentary loss of consciousness and very feeble convulsive movements. Reynolds has described two forms : (1) That without evident spasm ; (2) that with evident spasm. Such seizures are always fugacious, and consist merely in some transient loss of consciousness and very little or no convulsive movement. The tonic spasms prevail, if any, and the disorder of motility may often consist simply in the arrest of some act in the performance of which the patient is engaged. While playing the piano the patient's hands may for a moment remain suspended over the keys he is about to strike ; if eating, the hand which holds the fork may be arrested between the plate and his mouth. The attack consists sometimes in the rolling upward of the eyeballs, or when crossing the room the patient may stop, remaining quiet for an instant. Temporary unconsciousness, shown by cessation of conversation, by change of color, and absence of intelligent expression, accompanies the other trouble. In a well-marked attack of petit mal the patient may move his lips convulsively, and remain otherwise quiet, but bereft of consciousness, for one or two minutes.

The patient sometimes loses himself and loses the thread of the conversation, repeating what he has just said or showing his want of appreciation of what his companion has said. To this light grade belongs the case reported by Jackson of the individual who blew his nose upon a piece of paper and gave the conductor £2 10s. instead of twopence halfpenny.

The Major Attack.—An attack of epilepsy of the familiar severe form may or not follow an aura. The first intimation to the bystander may be a noise made by the patient, which is either a loud, startling, wild cry, or a gurgling groan due to compression of the thorax and the

forceful escape of wind through the vocal cords. There are three stages of the attack: (1) The stage of tonic convulsion; (2) the stage of clonic convulsion; (3) the reactionary stage.

The first stage of the attack is symptomatized by tonic spasms, which may be local or general, usually the latter. It is very often unrecognized, for its duration may be so short that it is lost in the stage of clonic spasms, which is much more protracted. There is usually unilateral seizure, the muscles of the face being primarily involved, then those of the hand and upper extremity, and then those of the lower extremity; and finally there is a general involvement, so that the patient may be in a position of opisthotonos. In some cases there is strong tonic contraction to one side, or pleurosthotonos. The notes of a case which illustrates the beginning and development of convulsion with reference to the parts involved, which I observed carefully, are the following:

Bindewald: Epileptic attack observed at hospital for paralyzed and epileptic, Sunday, Mar. 12, 1882:

1. Long, shrill cry which attracted my attention. It probably lasted five seconds. At same time patient threw up arms and became unconscious, and fell to floor. Nurses ran to him and placed him upon bed.

2. Tonic convulsions began by fine twitchings at right corner of mouth. These became gross, and were separated by succeeding long intervals. Eyes directed to left side, face pale.

3. In twenty seconds twitching began in right hand and arm, which were rigidly flexed (five seconds); then leg and foot of right side became agitated, the face meanwhile changing in color successively from red-gray to purple; lips purple, ears livid and purple, edges white; eyes still turned to the left, pupils dilated, eyes widely open; breathing stertorous and irregular.

4. General convulsions of right side.

5. Head suddenly twisted to left side; position of eyes the same. Chin drawn down, movements moderated; still livid. A fit of coughing and expectoration of much frothy mucus. Left side, with exception of head, not implicated. Whole attack lasted about one minute and thirty-five seconds. Deep sleep afterward, lasting forty-five minutes.

This attack was one of many in a confirmed epileptic, and is a fair example of those commonly met with, though not as general as we sometimes find. In most cases the attack appears to be very much longer than it usually is, and the phenomena noted above, which seemed to occupy a considerable space of time, really lasted but little more than a minute and a half. Axenfeld and Beau fix the average period of the attack as follows: "Duration of the complete attack, which Beau divides into four phases: first stage, tetanic stage, five to thirty seconds; second stage, clonic convulsions, from one to two minutes; third stage, stage of stupor, three to eight minutes; fourth stage, return of sensibility and intelligence. It is not complete until the end of from ten to thirty minutes."

To be more explicit, the manifestation of an ordinary epileptic attack of the more severe kind is very much like this: Usually without any warning to those about the patient he utters a shrill, peculiar cry of a character never to be forgotten if once heard, and then, perhaps throwing up his hands, he falls to the ground rigid and contorted. His body may

be arched laterally or antero-posteriorly, his legs are thrown out, his forearms flexed, and his fists doubled, the thumbs being beneath the other fingers. His face may be for a moment flushed, but the color recedes, and it assumes a dusky-bluish tint, the lips being ashy-gray. The eyes are usually open, and the balls are rolled up and the pupils widely dilated. The breathing may for a moment be suspended, but it soon quickens, and becomes labored and noisy, and the pulse grows hard and full. The tonic contractions are succeeded in a very short time by more or less violent clonic contractions, which increase in violence and rapidity; the jaws work and the lips are covered with foam, which is blown in and out by the rapid inspirations and expirations. It may be tinged with blood in the severe attack if the tongue is bitten, which is by no means an uncommon accident. The teeth are sometimes firmly set and the jaws locked. The head is usually drawn to one side in the first stage, but afterward may be rolled from side to side. The movements are now more or less general, and occasionally the agitation is so great that the patient throws himself from the bed on which he may be lying. The face grows more pale, or rather more livid, and toward the end of this stage there may be a puffiness and congestion such as are seen in partially asphyxiated individuals, for this alteration in color is due to dyspnoea and consequent imperfect oxidation. The patient may defecate or pass his urine unconsciously, and sometimes we find seminal emission. The movements, after a period varying from ten seconds to a minute or two, become less violent, and he may talk in a silly manner, as a person does who is recovering from profound ether unconsciousness; or deeply sigh, and he is restless. The pulse is now much weaker and more rapid, and may be irregular. The color returns to the face, the patient closes his eyes, and the body is covered with profuse perspiration. The fingers are unlocked and every evidence of spasmodic movement disappears. He falls asleep, and remains so for several hours, awaking with a confused feeling, headache, and no remembrance of the attack, and is only reminded that something has happened by his wounded tongue or lips, the bruises he has received, or by the information of friends. He looks jaded and tired, and is indisposed to exert himself for several days if the attack has been at all severe. The transition from the attack to the normal state is not always the same. Some patients do not sleep at all, but after being dazed go about their occupation. This is even true occasionally of the severe form of disease.

The usual termination of the attack is, however, by sleep preceded by a period of confusion. The patient, after coming out of the clonic stage, mutters incoherently. He is apt to pass large quantities of wind from his bowels, or vomits. This is attended by a subsidence of the spasmodic movements, and perhaps by oscillation of the eyeballs. The pulse loses its rapid, hard character, and the reaction brings with it diminished frequency of respiration and the evidence of exhaustion.

Special Symptoms.—The eyes are, as a rule, open, and, there being spasmodic movement of the ocular muscles, we find that the balls are either rolled up or directed away from the side in which the spasms begin. This is especially true in those epilepsies due to cortical disease, and the same law of conjugate deviation laid down by Bourneville may be remembered.

The pupils are dilated pretty much throughout the fit, though they may vary, and a transient contraction may occur at the commencement of the first stage. During the clonic stage, especially toward the end, they not infrequently undergo a species of oscillation. The interparoxysmal state is revealed by a very great mobility of the pupil, which has been observed by Gray and others. Gray is disposed to consider it a diagnostic indication of value, but so far I have found it only in two-thirds of my cases. Dilatation of the pupil I believe to be a very constant feature of epilepsy.

The ophthalmoscope reveals in certain cases an abnormal increase in the circulation at the fundus, in others a very decided emptiness of the retinal vessels. Jackson is disposed to consider that certain visual auræ depend upon spasm of the arterioles in this location. Loring, whose opportunities for research have been very great, is not disposed to attach much importance to the ophthalmoscopic appearances, at least during the periods between the fits.

The pulse of the epileptic between the paroxysms is small and irritable. Voisin has found the following changes: "Two or three seconds before the attack it becomes rapid, sharp, and the sphygmographic curves are higher, rounded, and nearer together. When the attack begins we see five or six little undulations in the course of the ascending line, and the curves are higher and more accentuated. Several minutes after the attack there is dicrotism, and the line of descent is very sharp, the angle with the ascending being quite acute. This form of pulse lasts an hour or half hour after the attack. There is in some cases great irregularity, with paroxysms of cardiac pain resembling angina pectoris. There is occasionally epistaxis or more marked hemorrhages." Parrot speaks of hemorrhages from the eyes and ears, and occasionally the cerebral congestion is so great as to result in cerebral hemorrhage in old subjects.

The temperature is usually lowered before the attack, but the surface temperature is increased during or after the second stage.

Cutaneous sensibility is often very much disturbed. Spots of hyperæsthesia and anæsthesia are sometimes left after the attack. The scalp is not infrequently exceedingly tender. The sensory troubles have been alluded to as prodromata of the ordinary motor attack. Some attacks of the sensory variety in which psychical excitement plays a part are characterized by unilateral and persistent formications.

A consequence of some epileptic paroxysms is the appearance of petechiæ, chiefly upon the face, neck, and upper extremities. The skin of old epileptics is harsh, cold, and rough, and the face is apt to be studded with spots of acne even when the patient is not taking the bromides. The hair is stiff and dry, and the ears and tip of the nose are apt to be the seats of a passive and old hyperæmia.

The urine of epileptics is apt to contain evidence of muscular waste, and an increase in the amount of earthy phosphates as well. Zapolsky found, however, that immediately after the attack there was diminution in the quantity of the phosphates. The occurrence of glycosuria has been noted by numerous clinicians. De Renzi¹ has published an interesting article. I have seen no less than six well-marked cases within two years in which constant glycosuria was a feature of the disease, but in two of

¹ *Gior. internaz. d. Sc. Med.*, Napoli, 1880, ii. 357-359.

the patients well-marked symptoms of disease of the pons were present. After the paroxysm it is by no means uncommon to find the urine loaded with albumen. Otto, Mabilie, Saundby, Bazin, and other writers speak of a transitory albuminuria. Kleudgen,¹ however, does not attach much importance to this feature, believing that the albumen is often due to semen.

The tendinous reflexes are frequently abolished during the attack, but not always so, and in several cases in which I was enabled to make a test during the convulsion I found that the patellar reflex was very active, and in one case elsewhere reported it was transferred. The skin reflexes are ordinarily exaggerated.

Tongue-biting is, I think, a more common feature of the nocturnal than the other attacks. It is rare in infantile epilepsy, and is always a bad feature. The wound is sometimes very serious, and cases are mentioned where the tongue has been severed. An occasional sequel of the attack is a urinary difficulty and vesical tenderness. It is sometimes connected with great urethral irritability and spasmodic stricture, which prevents the introduction of a sound or catheter. Romberg speaks of the supervention of asthma and dysphagia.

THE IMMEDIATE AND REMOTE EFFECTS OF THE EPILEPTIC PAROXYSM.—As a result of violence we often find wounds and bruises, quite rarely fractures, but more often dislocations. Cases have been communicated to me where as a result simply of the great muscular force the humerus has been dislocated at its superior articulation. Muscular pain of great severity, and sometimes of great persistency, follows unusually severe fits, and rupture of muscular substance is not uncommon. An epiolecranon bruise in one of my cases produced a severe neuritis which was very intractable. In old cases, according to Axenfeld, there may be great muscular hypertrophy, the sterno-mastoidii attaining the size of the biceps, and in other cases there is fatty degeneration. He also calls attention to defects that may be due to frequent exercise of violence upon bones through repeated exaggerated muscular contraction. Paralysis of nerves which supply convulsed members is mentioned.

The psychical effects are various. For several days following the attack there may be simply confusion of ideas, irresolution, or drowsiness, which subsides in a short time. In not a few cases I have regarded the attack as beneficial in the sense of an explosion of relief when perverted mental states had preceded it. In such persons the discharging lesion was followed by a very conspicuous restoration of the mental equilibrium.

Occasionally the attacks are terminated by great violence or screaming or the commission of purposeless acts.

Post-epileptic aphasia has been described by Winslow, Moreau, and others, and among my own cases of the sensory variety of this disorder I have met with speech disturbance. The aphasia is of short duration, and consists either in a total incapacity for verbal expression or a transposition. It is not rare for it to be associated with the commission of a number of quasi-automatic actions.

Unilateral epilepsies are quite apt to leave behind them a species of paresis which may last even for several days. The loss of power is confined to the convulsed members, and may be accompanied by tingling.

¹ *Archiv für Psychiatrie, etc.*, 1880, xi. 478-506.

In the greater number of instances, however, there is some central organic change, and the epilepsy is purely symptomatic.

Deafness, amaurosis, and other pareses of the organs of special sense are rare sequelæ of the epileptic state.

The remote effects of the grave disease are not so decided as when the patient has been the subject of *petit mal*. Slight repeated losses of consciousness are apt to be followed by mental decay. The ultimate result is mental enfeeblement, a progressive and very great loss of memory, which advances to such an extent that a veritable dementia ensues. With this there is usually a very decided perversion of the emotions and affections, so that a good-natured, amiable child may in a few years become everything that is bad and trying, and the acts of mischief are almost inconceivable. Theft, incendiarism, and various moral perversions are common in some chronic epileptics. The dementia, it is true, is tardy in its establishment, but it comes eventually if the individual lives long enough.

In some individuals there is a very early tendency to the development of mania; there is a certain periodicity about the explosions, and when established the excitement either precedes the attack by a few days or occurs shortly afterward. The violence is characteristically acute, and such insanity very often makes itself known in homicidal acts rather than in those of a suicidal character. Hypochondriasis is quite likely to follow continued epilepsy.

It is the rule for epilepsy to undergo decided modifications in the beginning of its course. The first attack may be simply eclamptic, without any peculiarities or definite character, and with recurrence there is a tendency to regularity and constancy in expression. Infantile convulsions, that may occur at any time after inconsiderable exciting causes, may eventually be confined to the early morning or night. So-called fainting attacks may precede *petit mal*, and headache may be the precursor of ill-defined seizures. So, too, the relation of grave and light attacks may vary. In the beginning there may be nothing but attacks of *petit mal*, while later these may be supplemented by severe fits, and even disappear entirely. So far as my own cases go, I find that nearly two-thirds of the entire number happen at night or in the early morning, while the others may occur in the day or at any other time, or by day and night. Besides the terms nocturnal and diurnal, we may use the word *matutinal* in relation to the time of attack. So far as the number of attacks is concerned, we find great irregularity. It is not always possible to count them, or even to recognize them, for the examples are numerous where nocturnal attacks have been undetected for years, and have finally been followed by fits during the daytime. I have cases who have seizures but once or twice a year, and others who have ten to forty or fifty daily. In some cases there may be eight or ten attacks of *petit mal* daily, and but two or three grave attacks during the week.

The statistics of Delasiauve and Leuret go to show that of 296 cases of epilepsy, the cases of general epilepsy were most common—that is to say, the attacks which occur both by day and night.

| | |
|---|----|
| Attacks occurring occasionally by day | 26 |
| “ “ habitually by day | 30 |
| “ “ only at night | 9 |
| “ “ habitually at night | 8 |

| | |
|---|----|
| Attacks occurring equally by day or night | 87 |
| “ “ in larger proportion by day | 70 |
| “ “ “ by night | 44 |

Delasiauve, Herpin, and others make delicate distinctions between the attacks, and the former grades the seizures beginning at accesses, and successively advancing to vertiges, accès intermédiaires, and attaques or accès complétés.¹ In fact, these are but varying degrees of violence of the discharge, after all. We thus have light discharges and severe discharges at different times, or, as the habit is established, only the light or only the severe, the manifestation depending probably upon the number of discharging cells and the importance of the exciting cause.

When the attacks occur in alarming frequency, as they sometimes do, the condition is known as the status epilepticus. Leuret had a patient who had eighty in two hours, and Delasiauve reports the case of a young man fifteen years old who had twenty-five hundred in one month. They may be so numerous as to be apparently continuous. The patient remains in a state of coma (the status epilepticus), with very high temperature. If he be not restored, he sinks into a deeper coma, and all the signs of collapse manifest themselves. Bed-sores form, œdema of the lungs ensues, and the patient dies. Happily, this condition of affairs is rare.

Delasiauve calls attention to the fact that the first two or three attacks that usher in this state do not usually attract much attention, but the succeeding ones are so violent as to immediately suggest violent consequences. In one of my cases the attacks, when they had once become numerous, were readily excited by the least jarring, noise, or handling, just as we find in strychnine-poisoning or tetanus.

Irregular Forms.—There are occasional cases of psychical or masked epilepsy, the study of which is intensely interesting. Such forms are characterized by perverted consciousness and a low degree of volitional direction which may vary from automatism to the undoubted exercise of complex functions of the mind, though badly co-ordinated. Mesnet's soldier, when subject to a paroxysm and apparently unconscious, would perform a number of suggested acts in a rhythmical manner and with no subsequent knowledge of the previous event: when started off by the word of command to march, he would blindly go on, marking time when he met with an obstruction until stopped, or when a paper and tobacco were placed in his hands he would proceed to roll an unlimited number of cigarettes.

Two cases of a more complex exercise of certain intellectual powers, while others were dormant, came under my observation some time ago. One of them was a young man of twenty-three, who had had irregular epileptic seizures for some years. He went to bed one evening as usual, arose, and breakfasted with his family without creating any suspicion that he was at all unwell. He then went down to his place of business, and after his arrival was sent to a distant part of the city for some tool. On his return down town he stopped at a tobacconist's and became involved in a quarrel with one of the persons in the shop. A policeman was called, who, more intelligent than many of his class, immediately detected something queer about the man, arrested him, and afterward took him to Bellevue Hospital. There he remained three days, and suddenly

¹ *Traité de l'Épilepsie, etc.*, Paris, 1845, p. 55 et seq.

returned to consciousness and a knowledge of his surroundings, but was entirely ignorant of his unfortunate experience. It is unnecessary to say his habits were perfectly good and he was not drunk at the time of the quarrel or arrest. His last recollection was that of going to bed the night before the day of his arrest.

Another case of unusual interest which came under my care, illustrating a phase of sensory epilepsy, is worthy of reproduction :

C. O——, aged twenty-two, is a reporter attached to one of the New York afternoon papers, who received a severe injury of the head when but three years old. He fell from the second story of an unfinished building to the cellar, striking the upper and back part of his head upon a beam. He was rendered unconscious, and remained so for a day or more. He recovered from the immediate bad effect, but has suffered from severe general headaches, which recur every week or so, with an increase in the amount of urine excreted. About six months ago he began to have epileptic convulsions of a violent character almost every day, and sometimes more often. These were precipitated by excitement, and he had a great many when worried about his wife at the time of her delivery. Upon one occasion he fell down stairs and injured himself quite severely. The attacks were, as a rule, preceded by an epigastric aura of long duration, and occasionally by a visual aura, and, according to the testimony of his associates, he became strange and queer. When in such a dazed condition he would restlessly wander about his office, and suddenly, without any cry, become convulsed. After the attack he slept soundly. The bromides of sodium and ammonium and digitalis did little or no good, but the bromide of nickel appeared to have some influence. During the past month he has had only two or three attacks, but these have been of a quite irregular character. He told me that there were times when he felt like doing himself an injury, and that he had impulses to kill some one else. His companions said he was irritable, pugnacious, and easily thwarted, and his brother-in-law stated that upon several occasions he had queer turns, when he would raise his hand to strike some member of the family—that he subsequently knew nothing of his conduct, and when it was detailed to him he appeared greatly astonished.

Mr. O—— came to my office in company with a friend at ten o'clock in the morning of December 27, 1883. He had had one of his attacks at the newspaper office, of rather more severe character than usual, at eight o'clock, with a psychical aura, during the existence of which he was very morose and sullen. Upon recovery he was speechless, though he could communicate by signs. Upon his arrival at my office his manner was composed and he appeared somewhat dazed. His pupils were dilated, but contracted readily to light. I asked him one or more questions regarding his inability to speak, which he perfectly understood, and when I gave him a pencil and a piece of paper he replied without difficulty in writing. When told to make a great effort to speak he did so, and I thought I detected the word 'To-day,' but he could not repeat it, though he tried and expressed great annoyance. He was unable to utter any sound except a sort of groan, which could not in any way be taken as an element of speech. I examined his larynx, but found nothing which could explain his impaired phonation, and I sent him to Dr. Asch, who found absolutely no abnormal appearances to account for the speech

difficulty. The patient could not phonate, and though he made attempts to enunciate the vowel-sounds, and the vocal cords were approximated, he made no orderly sound. Asch found a slight laryngitis of no importance.

The patient went home, and remained speechless all day, and was seen by my associate, G. de Forrest Smith, in the evening. What occurred during and after that gentleman's visit is contained in his notes: "I was called to see patient about 8.15 P. M. He was lying upon the bed, but had not slept; recognized me and motioned that he could not speak, and I found that he could only say one or two words, and this with the greatest effort, and so all my questions were put so that he could answer them by nodding or shaking his head. He knew that he had had an attack in the morning, that he had seen Hamilton and Asch, and recalled various incidents of the day, answering intelligently my questions in regard to them. He indicated by motions that his inability to speak was due to a lump in his throat. When asked if he had any trouble to think of the word he wanted, he shook his head, but shortly afterward hesitated in an answer, and when asked if this was due to his inability to think of the word, said 'Yes.' Was asked if he had any loss of power in either side, and he motioned to his right arm and leg, and said that he felt a numbness and pricking on that side. On his grasping my hands with his, the right was perceptibly weaker.

"At one time he seemed confused as to which was his right or left side, and put up both hands, and after looking at first one and then the other in a puzzled manner, at last decided correctly, then smiled apparently at his confusion.

"All this time he had been half lying on the bed. He now intimated that he was tired, put his head down on the pillow and began to belch up wind, and as he appeared about to vomit I called for a basin; but this was only the beginning of an attack; the muscles of the neck and right side assumed a state of tonic spasm, the extensors predominating, so that the head was turned a little to the left and forcibly thrust back into the pillow, and the right arm and leg were firmly extended. He remained in this position about one minute; then, taking two or three full inspirations, put his hand to his throat and said plainly, 'Something has fallen from there.' On being asked 'What?' he replied, 'A bone has fallen from my throat.' I told him it was well that the bone had fallen, as now he could speak. 'Why,' said he, 'I have had no difficulty in talking.' On being asked why he had seen Asch, he said 'Who is Dr. Asch? I never saw any such person.' Further questioning showed that all the occurrences of the day (except those which had taken place immediately before the first attack) were an absolute blank, and he thought it still morning. He asked the time, and I told him half-past eight o'clock in the evening. At this he seemed much surprised and said, 'Why, I went to work this morning; how did I come here?' I then explained to him that he had been ill. After further conversation he said he felt sleepy, and, after resting a few minutes, he arose, put on his slippers, and came out into the room. He walked with difficulty, because of the loss of power in the right side, which he said felt numb and sore, as if it had been pounded, also a sensation of pins and needles. After the attack his mind was perfectly clear, and he could talk as well as ever, and all that had happened before the attack in the morning he could remember per-

fectly well, but the interval between the two was a complete blank. His inability to speak seemed due, not to lack of knowledge of what he wanted to say, but rather to want of power to form the words, although there was no paralysis of the vocal muscles. When he did manage to say a word, it was invariably the correct one, but it was always done with the greatest effort. The day after the attacks he remained at home; the next day he went to work, but his head felt heavy and confused. Two days after he complained of a pressure on the left side and back part of the head; otherwise he was all right. At this visit he said that after I had left him on the night of the attacks he intently thought, striving to recall the incidents of the day, and after a time concluded he could remember being at Thirty-third street, but did not know how he got there. He thought he could recall going to see Asch, but would not know him if he should see him. I then asked him how questions were answered by him on that day; he answered he did not know, as he had not thought of that; then, after a few moments' reflection, said he must have written the answers. He was then shown some of the answers he had written, which he recognized, and by an effort of memory could recall some of the incidents of writing them. He was still unable to remember anything that occurred after his arrival home previous to the last convulsion."

January 27, 1885: This patient subsequently suffered from several attacks in which the psychical element predominated. His head presented a remarkable deformity, there being a prominence posteriorly which might be compared to a *caput succedaneum*, only it was entirely osseous. The upper margin was separated from the anterior parts by a deep sulcus.

Under such circumstances we find very often that acts of great violence are committed by such epileptics for which they are entirely irresponsible. Two or three cases of the kind occur to me now. One of them was a boy who always bit every one and everything—his family, the domestic animals, and inanimate objects; another, a most dignified and lady-like woman, who violently struck different members of her family; and within the past week a woman was brought to me who hurled a kerosene lamp at a perfect stranger with whom she was quietly talking before the seizure was precipitated. Numerous instances are related where individuals while in the masked epileptic state have wandered for long distances and committed a variety of purposeless acts, and undoubtedly many of the mysterious disappearances are of this order.

SENSORY EPILEPSY.—Some years ago Hammond referred to certain peculiar epileptic attacks in which sensory manifestations were very pronounced. To this condition he gave the name *thalamic epilepsy*, believing the condition to be one of the optic thalamus. Among the large number of unclassified and irregular cases reported by various authors there are many so much resembling each other that I think they should be relegated to a special place.¹ The notable examples of Sommers, Bergmann, Tagges, Guislain, and others belong to this category.

¹ I shortly afterward, believing the term a misnomer, invented that in use: "On Cortical Sensory Discharging Lesions or Sensory Epilepsy," *New York Med. Journal and Obstetrical Review*, June, 1882; also see "A Contribution to the Study of Several Unusual Forms of Sensor; Epilepsy which are probably Dependent upon Lesions of the Occipital Cortex," *New York Med. Record*, April 4, 1885,

The features of this form of epilepsy are (1) the expression of some hallucination (prodromal stage), or hemiopia; (2) supraorbital neuralgia; (3) aphasia, formication; (4) slight loss of consciousness, and little if any motor disturbance.

I may present two illustrative cases:

A few months ago I was consulted by a medical gentleman in regard to a patient who had for years presented a curious train of nervous symptoms, which afterward assumed a form leading me to think she might have sensory epilepsy. She would, in the presence of the gentleman who consulted me, who was a personal friend of the patient and a medical man, stop short in the midst of an animated conversation, look fixedly ahead, appearing momentarily lost, remaining abstracted for a short period, possibly a minute, and on recovering herself go on, finishing the sentence she had commenced before the seizure. At this time she constantly had hallucinations of a visual character, when she saw animals, birds, figures of men and women, who approached her, as well as a variety of other objects. A common hallucination, which had been repeated quite frequently, consisted in visions in which green leaves and white rabbits and other objects familiar to her in childhood figured extensively. Upon one occasion, while sitting in the drawing-room, opposite a door which communicated with the hall, she suddenly called her companion's attention to the hand of a man which she saw clasping the baluster rail. The hand was seemingly disconnected from the arm. She was somewhat agitated, and it was nearly half a minute before the vision was dismissed. Sometimes she would call attention to the hallucinations before the attack, but more often she became transfixed, apparently lost, and then recovering she described her visions minutely. She has apparently been able to foresee the attacks and ward them off by a strong voluntary effort. So far as can be learned, there is no hysterical element in the case, but her seizures are more frequent at the time of menstruation. In a private note it is stated that "the family history of the patient is very good, and she has always seemed remarkably healthy and robust, and has shown more than usual intellectual ability. She has appeared to persons generally to be of a contented, happy disposition. . . . At night, when she closed her eyes, she suffered from these hallucinations, especially after a day of fatigue. Her pupils are usually dilated, but her color undergoes no change during the seizure."

The second case is one of a more complex type:

J. B.—, a bright boy aged sixteen, was sent to me by F. H. Bosworth in April, 1883. He comes of nervous stock, his mother being subject to epilepsy, and his father is an eccentric man who manifests his mental peculiarities chiefly in a morbid restlessness and irascibility. There is a brother who is healthy. The attention of the parents was first called to the boy's condition by his recital of a sudden attack which occurred during the summer of 1882. While rowing upon a river he suddenly and completely lost the visual use of the right eye, so that in looking at a number of ducks swimming near his boat he failed to perceive those upon one side of the flock. This condition lasted for twenty minutes, and after a brief and severe pain over the right eye he became unconscious, the unconsciousness being preceded by a tingling and numbness of the hand, forearm, arm, and left side of the tongue. He has

subsequently had eight or ten of these attacks, of which the following is an example: Usually without any bad feelings, physical or mental, he, while engaged in any duty or at any time, suffers a sudden unilateral blindness. This is never gradual, and not like the form of amblyopia in which the visual field is gradually reduced. There is some hemichromatopsia. It would seem as if the retinal anæsthesia was unequal, for while usually the loss is complete and universal, it sometimes happens that there is only a limited loss. Upon one occasion, while reading, he suddenly lost the printed matter of the right lower half of the page below a diagonal line extending from the right upper corner to the left lower corner. There is never diplopia. This deprivation lasts anywhere from ten to twenty minutes; meanwhile, a distal anæsthesia, coming very gradually, involves at first the fingers of the opposite hand, and successively extends to the forearm, arm, and other parts, as I have already mentioned. There seems to be analgesia as well as anæsthesia, for a pin may be run into the muscles without producing pain, and upon one occasion the gum was freely pricked without any discomfort to the patient. It invariably happened that the cutaneous sensory trouble occurred upon the side opposite to the hemianopsia and neuralgia, and in the greater number of instances the left side was that affected. The third stage of the attack consists in migrainous headache of a very severe kind, and which sometimes lasts for an hour or more. There is a subjective feeling as if the eye was pushed forward. This disappears with nausea and relaxation. More often he loses consciousness when the anæsthesia reaches its limit, which seems to be the extension of the anæsthesia to the gums. Occasionally there are slight convulsive movements upon the anæsthetic side. While the attacks involve the left side of the body as a rule, it happens that when there is primary left hemianopsia and right-sided anæsthesia the boy becomes very much confused in speech, and sometimes is paraphasic, the trouble being but transitory. He is sometimes unable to speak at all, though perfectly conscious and in possession of his faculties. No pupillary disturbance has been noticed at any time. Upon two occasions there was a swelling of gums and tongue, which was not only subjective, but perceived by the mother. Occasionally he sees prismatic colors and rays before the blindness, but this has been only once or twice. During his early life he had attacks of slight numbness of the hands and feet which were not thought much of, and he had headache as well. He has been a somnambulist.

MORBID ANATOMY AND PATHOLOGY.—The literature of the experimental physiology of epilepsy is enriched by the observations of a variety of careful students, among them Sir Astley Cooper, Kussmaul and Tenner, Brown-Séquard, Nothnagel, Schroeder Van der Kolk, Pitres, Hughlings-Jackson, and the followers of the localization school, as well as many others more or less distinguished.

The experiments of many of the early writers were directed for the purpose of ascertaining the relations of circulatory variations to convulsive seizures, and the most notable were those of Burrows and Kussmaul and Tenner. These latter produced compression of the carotid arteries, and instituted cerebral anæmia by free and exhausting hemorrhages. As a consequence, the emptying of the cerebral vessels was followed by a loss of consciousness and by epileptiform convulsions, and it was neces-

sary to produce the same result to compress all the great afferent vessels of the brain. The experience of surgeons generally is, that ligation of the common carotid upon one side of the neck is sometimes very apt to produce an alarming anæmia, with occasional convulsions, and sometimes fatal consequences.

The experiments of Hall, Landois, Hermann, and others, as well as those of the writers just mentioned, show that carotid compression results in capillary anæmia and venous hyperæmia, and that with cessation of this pressure there is a sudden congestion of all vessels. The susceptibility of the brain is greatest at its posterior part and between the optic thalami and the cord. When the bulb was subjected to sudden changes in its nutrition—such, for instance, as followed the experiments of Hermann, who ligated simultaneously the superior and inferior venæ cavæ of a rabbit—there were not only convulsions, but various cardiac and other disturbances which were undoubtedly due to central impairment of function. Kussmaul and Tenner conducted their experiments with watch-glasses luted into the cranium—a procedure which, however, at best, is unreliable.

Brown-Séquard some years ago in part established an important pathological truth, the theory of epileptic zones, and demonstrated in certain animals that bruising and injury of the great nerve-trunks, especially the great sciatic, would give rise to epilepsy, and that irritation of certain tracts would precipitate the paroxysms. He further announced that the progeny of animals in whom epilepsy had been thus induced very frequently inherited the epilepsy of the parent. By some it was held that such epilepsies were purely peripheral, and Brown-Séquard even believed in spinal epilepsy. His spinal epileptic theory has, for the most part, been explained by the anatomical researches of Hitzig and the doctrine of interrupted spinal inhibition. In fact, many of the spinal epilepsies are examples of exaggerated reflexes.

The epileptiginous zone theory, which, while it induced many to believe that the disease might have its origin outside of the brain, gave rise to the false assumption that attacks with distal auræ were primarily non-cerebral, has been discarded, and most observers have arrived at the conclusion that even in these cases the first explosion is due to some cerebral cell-discharge.

Hughlings-Jackson's grand work has revolutionized the views held prior to his first published writings, about twelve years ago. He believes that any part of the gray matter may, through over-excitability, give rise to convulsive attacks.

The production of convulsions by cortical irritation is now an old story.

The experiment of Pitres and Frank¹ bears upon the sensorial function of the cortex in showing that, when the cortex is irritated, epileptiform convulsions follow, but if the exposed surface be subjected to the ether spray the same irritation will only produce definite movements, but no convulsions.

The investigations of Van der Kolk especially, and his followers, certainly give the medulla an important place as the locus morbi of the malady; and it must be assumed, bearing in mind the existence of the vaso-motor centres of Dieters and the presentation of symptoms indicative

¹ *Gazette des Hôpitaux*, No. 38, 1883.

of disturbance at the floor of the fourth ventricle, that the most important pathological changes must be looked for in this part of the brain.

Jackson's cortical explanation is, however, fully in consonance with the medullary theory. If we study the different stages of the attack, we shall find that there is probably a suspension of cortical inhibition—that a derangement of the cortical cells or discharge may cause a resulting disturbance in the bulb. On the other hand, a reflex irritation through the pneumogastric or from some distal part brings about the same disturbance of equilibrium. There is anæmia due to irritation of the vaso-motor centre, an inhibition of the great ganglion-cells, and a disturbance of function of the important cranial nerves. The primary anæmia and unconsciousness are accounted for by this primary irritation of sympathetic filaments and vascular constriction; the secondary hyperæmia is explained by the experiments of Kussmaul, which demonstrated the succeeding congestion; or by irritation of the spinal accessory and contraction of the muscles of the neck and compression of the large veins. The pupillary, ocular, respiratory, and other symptoms indicate the disturbance of the nerve-nuclei in the bulb. The respiratory difficulty and the interrupted decarbonization of the blood undoubtedly account for the secondary unconsciousness.

Van der Kolk¹ in localizing the lesion in the medulla found capillary dilatations in the neighborhood of the hypoglossal nuclei in tongue-biters. In epileptic patients who were in the habit of biting their tongues during the fit the vessels were wider than in those who did not bite the tongue, on an average in the course of the hypoglossus by 0.096; in the corpus olivare, which certainly here plays an important part, by 0.098 mm.; and in the raphé by 0.055. In those who did not bite the tongue, on the contrary, the vessels in the path of the vagus were 0.111 wider than in those in the first, Table A.²

Nothnagel³ is of the opinion that the anæmia of the brain is not the cause of the convulsions, but that the "excitation of the vaso-motor centre and that of the centre for the muscles are co-ordinate—that both go on side by side, and are independent of each other."

He by this theory explains the occurrence of those forms of petit mal in which there is loss of consciousness without convulsions, and, on the other hand, twitchings before the coma.

The best argument in favor of this hypothesis is in Jacksonian epilepsy, when monospasms exist oftentimes with a succeeding extension.

In those cases which are the outgrowth of migraine the pathological condition is probably an exaggerated tendency to angio-spasm, the original impaired vascular tonus in the beginning giving rise simply to pain and lesser troubles, while after repeated changes of calibre not only nutri-

tive alterations ensue, but hyperexcitability of the bulbar convulsion centres as well.

The labors of those who have endeavored to connect epilepsy with cerebral-tissue alterations have been attended by nothing very definite or positive, so far as pathological explanation is concerned. The post-mortem appearances have varied widely, and the only conclusion to be reached is that which shows that almost any morbid gross alteration of the cerebral mass may be symptomatized by convulsions, but such a production of paroxysmal trouble is much more likely to be the case, and in a more definite manner, when the cortical motor-centres are subject to destructive disease or irritative pressure. This is even not always the case, for numerous cases of injury of the paracentral lobe have been recorded with no showing of resulting convulsions. The long list of autopsies which I will not here consider show that an epilepsy may owe its origin to the pressure of a spicula of bone, or to the pressure exercised by depressed fragments of the same—to tumors or adventitious products, meningitis, cortical encephalitis, vascular degeneration, ventricular œdema, contusio-cerebri, and many other morbid processes which result in rapid or tardy degeneration. Of course, in such cases the genesis of the disease depends not so much upon the nature of the lesion as the location. The fruitful collections of cases of Ogle and Jackson are full of examples of limited growth or disease involving the cerebral cortex, while numerous cases collated by other writers show disease of the bulb or various peripheral parts which have been closely connected with the growth and behavior of the affection.

Several able pathologists have independently and repeatedly found that sclerotic degeneration of the hippocampal folds often existed. Delasiauve and Lébert first observed this lesion, but many modern authorities—among them Meynert, Nothnagel, and Charcot—who have also found this appearance, regard the change as of purely secondary, and consequently unimportant, character.

Tamburini¹ reports a case of hemiplegic epilepsy with induration of the left optic thalamus and the left cornu ammonis, in which aphasia existed. Pfleger² and Henkes have also found the sole lesion to be induration of the cornu ammonis. Of Pfleger's³ 43 autopsies, atrophy and sclerosis of the cornu ammonis were found twenty five times, and it was noted that the extent of the morbid change bore relation to the violence and frequency of the seizures.

In many examples, especially where the disease has been found to be unilateral and associated with more or less hemiatrophy, the autopsy disclosed a corresponding hemiatrophy of the brain. Many such cases are reported. I have frequently found epilepsy in association with cerebral hypertrophy, and as a symptom of cerebral tuberculosis it has long been recognized, and numerous cases are reported in which for a long time the paroxysms were the only manifestations of the condition. In one of these cases, reported by Lays,⁴ the bulb was found involved by tuberculous matter.

Convulsions have very frequently been noted in association with imperfect cerebral development, and Écheverria laid great stress upon the hyperplastic increase in volume of certain parts of the brain.

Marie Bra¹ has thus summed up her conclusions relating to the morbid anatomy of epilepsy:

"1. The mean weight of the brains of epileptics is less than the physiological mean.

"2. The cerebellum is greater than the physiological mean.

"3. There frequently exists an asymmetry between the lobes (not peculiar to epilepsy). The increase of weight is sometimes found on the right and sometimes on the left side. Equality is the exception.

"4. In no form of mental disease (excepting perhaps general paresis, which is accompanied also by epileptiform crises) have we met with so marked and constant a variation between the weights of the hemispheres as exists in epilepsy."

Drasche, Green, Greenhow, Löbel, and others have detailed cases in which tuberculous deposits were undoubtedly the causes of the disease.

Kussmaul and Tenner, Hoffman, and others have held that a stenosis of the superior part of the vertebral canal may explain, through pressure upon the cord, the genesis of the attack, and Kroon found asymmetry of the medulla oblongata.

The microscopical changes that have been found in brains where no gross lesion was apparent are by no means distinctive. I have myself examined the brains of many epileptics with discouraging results. The varying granular cell-degeneration, capillary dilatation, and exudative changes are common enough. In several cases of cortical epilepsy I found more or less advanced degeneration of the great cells in limited regions.

By far the most important and exact changes are those observed in the cases of sensory epilepsy. I have elsewhere collected some continental cases. In brief, areas of occipital softening or degeneration have been discovered in those cases with hallucination, sensory expressions, and hemiopia. In one case attended by hallucination of smell the autopsy disclosed the following:

M. M——, was a stout Irish woman about forty years of age. She had suffered from a light form of epilepsy dating from the tenth year, and resulting, as she stated, from a fall, when she struck her head and was unconscious thereafter for some hours. No scar was visible, however. No satisfactory history could be obtained regarding her early life and the first paroxysms. In the beginning these were rather frequent, and she had as many as four or five a month. They afterward diminished in number and severity, and for many years she had but three or four in the course of the year. They were not very severe, and she was enabled to pursue her work as a housemaid, but did not keep her places for any great length of time. She rarely bit her tongue, but usually frothed at the mouth and became livid and convulsed for a short time. There was no history of one-sided spasms. As I have stated, I could gain no accurate account of the previous attacks, except that she nearly always had an aura of a peculiar character, which was a prominent feature of the seizure and very pronounced. She suddenly perceived a disagreeable odor, sometimes of smoke, sometimes of a fetid character, and

¹ Referred to by Axenfeld.

quite uncomplicated by other sensory warnings; and afterward became unconscious, and remained so for two or three minutes. She was invariably able to describe her sensations when she recovered, which she always did when I asked her, comparing her warning to the smell of burning rags, to the smell from a match, and, as she expressed it, it sometimes rose up in her head and choked her. She was under my observation for one or two years, but eventually developed phthisis, and died, her attacks occurring from time to time until her death.

Besides well-marked tuberculous lesions in the lungs, there was little of interest so far as the visceral examination was concerned. The brain was removed and its peculiarities were carefully observed. A great quantity of fluid was found, especially at the dependent portions of the membranes and in the ventricles, while the dura was thickened and pearly in spots. There was a condition that might be likened to a low grade of hemorrhagic pachymeningitis, and at the base of the brain old plastic changes were found, there being adhesions, especially in the region of the middle lobes, but more particularly on the right side and near the median line. The brain as a whole was small, and weighed forty-one ounces and a fraction. The sulci were deep and gaping, and the convolutions were distinct. There was no atrophy of the fore-brain convolutions, and no other pathological appearance was presented except that found in the meninges, but at the lower part of the temporo-sphenoidal lobe of the right side an appearance was found of an exceedingly interesting nature. At this point a decided shrinkage of tissue was discovered, with depression and adhesion of the pia, the induration involving the uncinate gyrus and parts of the adjacent convolutions, as represented in the drawing.

FIG. 27.

Lower Face of Right Hemisphere.

No induration or softening of the great motor tracts was observed, and the optic thalamus and parts adjacent were uninvolved, as was the cord. An attempted microscopic examination, undertaken some months subsequently, was unsatisfactory, because of the bad condition of the brain, the preserving fluid having been improperly made. The olfactory nerves were not involved. The third frontal convolution was examined, but no disease was found there. Consequently, it is to be inferred that no lesion of the external root of the olfactory nerve existed.

DIAGNOSIS.—Having spoken of epilepsy as in most instances a symptomatic disorder, it would be proper to confine this section to the differentiation of the simpler and more classical form of the idiopathic disorder from certain purely eclamptic attacks or those due to cerebral tumor or

coarse degeneration. The epileptic attack itself is to be considered from its time of happening, its duration, the element of unconsciousness, its associations, and the antecedent history of the individual. It may be confounded with the similar phenomenon dependent upon cardiac weakness, uræmic poisoning, toxic or alcoholic saturation, etc.

Of course, when we find recurring seizures with a certain amount of what Carter-Gray calls quasi-periodicity, preferring perhaps the night, the early morning, or only the daytime, we are almost sure of epilepsy. This supposition is strengthened by the association with attacks of petit mal. The duration of an attack, which may be from a few seconds to several minutes, is also a guide, for in certain toxic and other paroxysms the rule is for a succession of attacks to occur.

The question of consciousness is one that has drawn forth a great deal of discussion, especially with reference to medico-legal cases. I think the majority of clinicians are agreed that loss of consciousness is an absolute belonging of epilepsy, yet there are cases in which the lapse is scarcely perceptible. It is a dangerous precedent to establish, for the convulsive symptoms in such cases are taken from the epileptoid category. It is quite true that there are many hemi-epilepsies in which the intellectual condition is one that may easily be mistaken. I have seen numerous cases in which an apparent conservation of consciousness remained throughout a slight monospasm, but I do not feel at all sure of this; and in cases of aborted or masked epilepsy there is a dual mental state which would readily deceive the lay observer. The case of Mrs. S— is an example of this kind. After the obvious subsidence of the dramatic and conspicuous feature of the fit she remained for hours and days in a state of undoubted transposition, performing acts which required something more than a high degree of automatism—going to the table, talking about certain subjects which were suggested, with apparent ease, but not connecting them intelligently with her surroundings, as she would before and after the epileptoid state. After a time she apparently resumed her normal state, but was entirely unconscious of the happenings of her previous hours or days, not even recollecting her simplest actions. Julian Hawthorne's hero in *Archibald Malmaison*, though not drawn by a physician's pen, suggests the state of which I speak, and it has the merit of being based upon one of the elder Forbes Winslow's interesting cases.

When we find paroxysmal attacks occurring in individuals with atypical heads, thick swollen lips, scarred tongues, and irregular teeth, we may strongly suspect the patient to be epileptic. To these we may add the appearance of the eyes, the fishy, lack-lustre expression which betokens old epilepsy. The hands are clammy and the skin mud-colored; the hair is dry and coarse; and the body often has a death-like odor.

In children, certain mental peculiarities are to be inquired into. Unnatural brightness or dulness—what may be called the clumsy organization—is often present, and the muscular use is often imperfect. We find that there is often but little nicety in walking, in using the hands, in speaking, or after learning to write there is an incapacity, with ever so much teaching, to develop a character or style. Such children can never become ambidextrous. These little points may seem trifling, but to the physician who carefully studies his cases they may prove of great help. The history of the nights may often lead to the discovery perhaps of a

long-existing nocturnal epilepsy. Incontinence of urine, blood upon the pillow, nightmares, morning headache, and petechiæ betoken unsuspected night attacks; and Le Grand du Saulk mentions the case of a young Englishman who committed a purposeless crime and was discovered to be epileptic, the diagnosis being confirmed by an antecedent history of nocturnal seizures, and subsequent watching resulted in the discovery of many night attacks.

As to special conditions with which the epilepsy may be confounded, I may refer to cardiac weakness. It not rarely happens that simple fainting attacks are confounded with those of an epileptic nature. Such is the case more often in heat-prostration, when some rigidity attends the loss of consciousness. The duration of such a state, the condition of the pulse and color, however, will easily clear up any doubts upon the part of the observer. The existence of a cause should also be considered, and the fact that usually the epileptic paroxysm is sudden, while a feeling of depression and feebleness precedes the fainting attack, should be remembered. I may present in tabular form the points of difference:

| EPILEPSY. | SYNCOPE. |
|--|---|
| Loss of consciousness sudden. | Loss of consciousness follows feeling of faintness. |
| Period of complete unconsciousness usually short. | Unconscious throughout, no convulsions. |
| The existence of auræ of a well-defined type. | The existence of preliminary vague prostration, nausea, and irregular heart action. |
| Often involuntary discharge from bowels and bladder. | Quite rare or never. |
| Patient usually falls into heavy sleep or is indifferent after convulsion. | Afterslight weakness patient is anxious and worried, and quickly seeks relief. |

The difficulty of diagnosis, however, is only in cases of *petit mal*.

There are light forms of auditory vertigo that may resemble vertiginous epilepsy. In the former there is never loss of consciousness, and the patient refers to the rotary character of the vertigo. A history of antecedent attacks, tinnitus, aural disease, and a certain constancy which is not a feature of *petit mal*, may be mentioned.

There are cases, however, which are puzzling, and come under the head of auditory epilepsy rather than auditory vertigo; and in these there is a multiplicity of expressions, the auditory symptoms predominating.

Of uræmic convulsions it is hardly necessary to speak. There is a previous history of renal disease which the microscope and less delicate tests will reveal, and clinically there is antecedent headache, some stupidity, and not unrarely thickness of speech and somnolence. There are some cases, however, which are obscure. I have known patients with chronic renal disease—such as waxy kidney, for instance—to develop a species of epilepsy, the paroxysms recurring from time to time and behaving very much as the idiopathic disease would; and their occurrence would mark some imprudence in diet or exposure, and their disappearance an improvement in the patient's general condition. The attacks were not classical, inasmuch as there seemed to be but one stage of violent clonic convulsion, preceded by intellectual dulness, and followed by a semi-comatose condition which was far more profound than the somnolent

stage of epilepsy. The movements were not accompanied by a great degree of opisthotonos or pleurosthotonos.

Alcoholic and absinthic epilepsies are usually preceded and followed by symptoms indicative of profound saturation.

The consideration of hysterical epilepsy may be found elsewhere, but it may do to briefly refer to some cases which do not present the phenomenon first described by Charcot and Bourneville. The ordinary hysterical attack is never attended by loss of consciousness, by any of the pupillary changes so constant in epilepsy, by the mobility of the pupil between the attacks which is present in a large number of true epileptic individuals. There are never the succeeding changes of color, and the seizures are commonly produced or attended by some emotional disturbance, or are associated with ovarian disturbance.

Epilepsy is occasionally simulated by malingerers, and sometimes the skill of the subject is so great as to even deceive the practised eye. Prisoners, soldiers, and litigants may counterfeit an epilepsy, and go through with great personal suffering to accomplish their purpose. "Clegg, the dummy-chucker," whose remarkable case has figured in the medical journals, upon one occasion threw himself from an iron platform to the stone floor of the jail, nearly twenty feet below, to convince a suspicious physician of his honesty. The simulator rarely bears close watching. The dilatation and contraction of the pupil cannot be simulated, nor can the corneal or pupillary insensibility. The fraud cannot voluntarily change his color, as is the case in true epilepsy, and as a rule the thumbs of the impostor are never flexed, as they should be. Suggestions for a purpose are readily heard, and sometimes adopted, by the apparently unconscious man. Gottardi¹ lays great stress upon the use of the ophthalmoscope as a means of detecting simulated epilepsy. He calls attention to the frequency of retinal changes with facial asymmetry and other evidences that suggest cerebral disease or non-development. Gottardi has found that the pulse in true epilepsy is always lower after an attack, but it soon reaches its normal standard.

The differentiation of idiopathic epilepsy from that due to syphilis is possible when we consider the element of pain. Besides the tibial pains of syphilis, the epilepsy thus produced is often preceded by intense frontal headache, while that of ordinary epilepsy follows the attack. The syphilitic epilepsy is not attended by so great or continued a loss of consciousness as the non-specific form, and the movements are apt to be most violent on one side or the other. The association of the attacks with various bodily signs, such as nodes, old scars, alopecia, erosions, etc., and in connection with possible cranial nerve-paralyses, will throw light upon its true character. The paralyses referred to seem most frequently to involve the motor ocularis, abducens, and patheticus. Syphilitic epilepsy, too, is quite irregular in its time of manifestation, and is not unrarely followed by aphasia; but the interparoxysmal mental state is one of extreme dullness, memory being blunted and there being a peculiar hebetude.

PROGNOSIS.—Within the past quarter of a century the ideas of the medical profession regarding the curability of epilepsy have certainly undergone a change. The statistics of Bennett and others show that since the introduction of the bromic salts the proportion of cures has

¹ Abstract in *Journal of N. and M. Dis.*, Oct., 1881, p. 843.

been decidedly increased. Nevertheless, the disease is a most discouraging and troublesome one to manage, and especially is this the case when it assumes the form of *petit mal*. The rapid recurrence of light attacks is, as has already been said, very apt to lead not only to mental enfeeblement, but is very often followed by very severe paroxysms.

Epilepsy of a more or less constant form, in which the seizures resemble each other, is far more incurable than that of variable type; for example, we find that unilateral seizures are much more apt to be associated with established cortical disease than when they are general and simply explosive manifestations. It has been held that a tendency to permanency is marked by a diminution in the extent of the interval. This is by no means true. I have had cases under observation for ten or twelve years in which attacks separated by intervals of six months or one year marked the course of the disease, in which frequent initial attacks were present. These cases I regard as very bad so far as prognosis is concerned. I much prefer a history of irregular and comparatively disorderly attacks. In female subjects the menstrual influence is not always a bad factor. When we are enabled to remove some production of an exciting cause in connection with the catamenia the prognosis is more hopeful; but an opinion must be expressed with great caution, especially in those cases beginning at an early age and not after the establishment of the menses. Traumatic cases are not always bad, but those in which the element of heredity plays a part most certainly are, Herpin and Gowers to the contrary; and though these cases for a time do well under treatment, its good effects are not constant. Individuals with misshapen heads, whose deformity suggests premature sutural ossification, are not susceptible to the influence of treatment, and all other osseous changes, such as exostosis, plaques in the dura, and bony growths, whose existence can only be guessed at or inferred from suggestive appearances elsewhere, give rise to a variety of epilepsy which is beyond the reach of drugs. With symptomatic epilepsies the case is sometimes different, for while the seizures which arise from the irritation of a cerebral tumor are almost as hopeless as the form I have just mentioned, we know from experience that the epilepsy of syphilis and other allied diseases, and those of toxic origin, with the exception sometimes of those occasionally due to alcohol or lead, are curable. The meningeal thickening of alcoholic origin or the encephalopathy of lead may be the pathological bases of very intractable paroxysms.

So far as age is concerned, it may be stated that many eclamptic seizures of young children which are due to well-recognized irritable causes are promptly cured if there be no hydrocephalus or preossification of the coronal sutures, and if the epileptic habit is not established. The epilepsies of six or eight years' standing are not encouraging from a therapeutic point of view, and those of advanced life developing in aged persons are equally unfavorable.

The treatment of epilepsy due to heat-stroke is by no means satisfactory, and, though the attacks are often separated by long periods, they are apt to recur in spite of drugs.

Gowers has prepared several valuable tables which show the influence of age upon recovery. He says: "The following table shows that age has a distinct influence on prognosis. The percentage of the unimproved

cases to the whole is 30 (43 : 143 : : 30 : 100). The percentage of the cases commencing at each age arrested and unimproved is stated, and between brackets is indicated the excess of the arrested or unimproved cases at each period of life over the proportion for the whole 30 and 70 per cent. respectively :

| | Cases. | | Percentage. | |
|-----------------------|-------------|-----------|--------------|-----------|
| | Unimproved. | Arrested. | Unimproved. | Arrested. |
| Under 10 | 14 | 29 | 32.5 (+ 2.5) | 67.5 |
| From 10-19 | 23 | 45 | 34 (+ 4) | 66 |
| 20 and over | 6 | 26 | 19 | 81 (+ 11) |
| | 43 | 100 | 30 | 70 |

Thus, the proportion of the cases commencing under twenty in which arrest was obtained is considerably less than the proportion of cases commencing over twenty, the difference amounting to about 13 per cent. The period of the first twenty years of life at which the disease commences has little influence, but the prognosis is little better in the cases which commence under ten than in those which commence between ten and twenty : arrest is more frequently obtained. The cases which commence in women at the second climacteric period are also obstinate, although not sufficiently numerous to be separately given."

He also finds, from an analysis of the same cases, the fact noted by others, that the prognosis is favorable in inverse proportion to the duration of the disease.

Attacks which chiefly occur in the daytime are much more amenable to treatment than the nocturnal seizures, and especially is this the case in the tongue-biting form. Sudden blows upon the head or falls have been known in isolated cases to effect an amelioration in the patient's disease, but these examples are rare.

The existence of an aura is much better than if none existed.

Death from the attack itself is rare, yet in the large pauper institution with which I was connected for many years I have known of several cases. More often the death results from asphyxia resulting from a bolus of food which chokes the patient or from a fall in some dangerous place—into the fire or elsewhere. Accidental death from drowning is more common than any other form.

The status epileptica into which patients sometimes pass who have had many convulsions is occasionally a fatal termination of the malady, and is always a serious feature.

The influence of different epochs in life is worthy of consideration : of menstruation, of marriage, of pregnancy, and of the menopause there is much to be said. I have sufficiently spoken of the establishment of the menstrual flow, and I would only add another word of caution against giving a too favorable prognosis except in those cases of very recent origin. Marriage appears to have very little to do with changing the attacks, unless they be of an hysteroid character. I have never known epilepsy to influence the course of a pregnancy in any unfavorable way, and I think this has been the observation of others. Gowers refers to cases in which the attacks ceased during the time the mother was carrying the child.

The occasional bad influence of the pregnant state has been illustrated

by a case reported by Terrillon.¹ This example was a woman who had been the victim of epilepsy of hereditary origin since her seventh year. At the commencement of menstruation her attacks became periodic, and recurred every two months, and she had several two or three days before the flow. Two pregnancies followed several years afterward. During the periods they were increased in number and severity, and occurred several times daily. She had more attacks at this period than in all the time after delivery.

I have found that the relief of uterine flexion or the establishment of menstruation has exercised a decidedly modifying influence for the better in several cases.

Sometimes the disease is interrupted by the menopause, but very often in my experience it has changed in type and been followed by mental degeneration.

The prognosis of the epileptoid mental state is serious in the extreme, and even when in early life the attacks are aborted or changed to perversion of the intellect or emotions existing as a complication, the hope of cure dwindles almost to nothing.

The spontaneous cure of epilepsy is rare. Its course, however, is more often interrupted by some intercurrent disease. Of 33 cases observed by Delasiauve in which there was some complicating disease, such as erysipelas, pneumonia, pleurisy, acute articular rheumatism, burns and contusions, scarlatina, erythema, or the condition of pregnancy, it was found that in 25 cases there was a decided improvement (une heureuse influence), and in 8 only was there no modification of the attacks. Axenfeld is disposed to believe that acute and febrile disorders more decidedly influence the course of epilepsy than those of a chronic nature. The influence of either may be small or may diminish the number of attacks without curing the disease.

TREATMENT.—The treatment of epilepsy depends so much upon the form of the disease that no arbitrary rule can be laid down upon general principles, and we must bear in mind the necessity for removing the exciting causes if possible, the preservation of the balance of cerebral blood-pressure and cell-equilibrium, and the nutrition of the cerebral mass. It may be our purpose to remove various toxæmic or cachectic states as well. As a minor division of treatment we must consider the abortion of the attack when auræ are detected. It has been the custom, I think among too many, to manage the disease in an empirical manner, depending upon some routine course of treatment, such as the indiscriminate use of the bromides, for example. I am convinced that the intractable character of the disease has come to be greatly exaggerated through failures attendant upon the wholesale use of the bromic salts, without regard to the indication in each particular case. It behooves us first to select a reliable bromide, and then to give it with relation to the time of the fit, its severity, and the condition of the individual. The importance of this has impressed me very often. An equally divided daily dose will not do a patient who has matutinal attacks the same good as will a large dose at night, and in certain anæmic individuals the bromides very often increase the attack. Then, too, the cases in which seizures of petit mal predominate are not benefited to the extent that those are in which

¹ *Annales de Gynécologie*, June, 1881, p. 401.

the repetition of severe attacks is the feature. The bromide should always be well diluted and given when the stomach is empty or nearly so. The bromide of sodium is, to my mind, the most serviceable salt, and when given alone or combined with the bromide of ammonium is better than the potassic salt or the various others. It should be carefully kept in solution or in waxed-paper powders in a tight preserve-jar. As to its method of administration, I much prefer the use of a solution which shall combine other adjuvants which I will presently mention, and separate powders as well, which may be used to reinforce the dose. The latter are to be employed by the patient in the event of an unlooked-for series of attacks, and are to be used to the point of producing mild bromism at the time. In certain cases it is all-important to take into consideration the condition of the heart. In some cases where there is manifest and continued cerebral congestion, with full vessels and hard pulse, I have found that the combination with chloral or aconite was desirable. In other cases where the heart's action was irregular and weak my experience with digitalis and nitro-glycerin or with strychnine was most happy. In those cases that passed large quantities of clear urine of low specific gravity the action of nitro-glycerin and digitalis has been most prompt, and the same has been true of epilepsies of migrainous origin.

There have been various methods of using the bromide suggested which are more or less practical. The writers of a few years ago suggested the prompt production of bromism—a state in which the patient should be kept for a long time. This I strongly disapprove of, not only because the mental and physical depression is a very disagreeable and sometimes permanent condition, but because I have found that the attacks are often increased after a time, though at first they may have been suppressed. Others believe in giving the bromides at intervals, with periods when no medicine at all is administered.

For my own part, I am in favor of the establishment of a mild bromism which does not extend beyond a slight anæsthesia of the fauces or the appearance of slight acne. If I find it necessary to increase the dose, I give cod-liver oil, iron, and bark or some of the many preparations of the hypophosphites for a time; and they do not diminish the specific effects of the drug to any great extent. In the event of a series of attacks I direct the patient to take an extra dose at such time as will anticipate the seizure.

This treatment should be kept up for at least two or three years after the attacks have disappeared, and it may be even necessary to continue a bromide course in a small way for an unlimited period.

If there be an hysterical element, or if ovarian excitement is supposed to have anything to do with the attacks, the combination of cannabis indica is strongly recommended. This suggestion holds good in the cases where migraine is associated with the epilepsy, or the latter is an outgrowth of the former.

Next to the bromides of potassium and sodium I have been very successful with the nickel bromide. I find that it is retained with little trouble, producing no gastric derangement if taken after eating. A syrup prepared by most of the good pharmacists is preferable to any other method of administering the salt. Quite recently Leaman¹ has reported

¹ *Med. News*, Apr. 18, 1885.

two cases of severe epilepsy which were greatly benefited. His conclusion is that it does most good in the form of the disease when the attacks are separated by long intervals.

The bromate of potassium, which has been used by Weir Mitchell¹ and Hinsdale, may be worthy of a trial. It should never be given, however, in larger doses than five or ten grains thrice daily. These investigators found that thirty grains slowed the heart very considerably, and forty grains produced watery discharges from the bowels and drowsiness. In their hands, notwithstanding these disagreeable effects, it controlled the seizures. The hydrobromate of conia is a comparatively new remedy which has been recommended. My own experience does not support that of Wolfenden.² Severe cases were treated by him with benefit. The dose he recommends is half a grain, and not more than four and a half grains are to be given in twenty-four hours. Headache and dizziness attended its use.

Erlenmeyer³ is an advocate of the mixed treatment, and his best results have been obtained by combining the bromides of potassium, sodium, and ammonium in the proportion of 1 : 1 : $\frac{1}{2}$. He thinks much greater permanency of effect follows such a combination. A curious result witnessed by this author is the fact that the acne produced by one salt given alone is apt to disappear when the combination is administered.

A solution of hydrobromic acid, prepared after Fothergill and Wade's formula, is recommended by H. C. Wood of Philadelphia,⁴ who presented the record of its use in twelve cases of obstinate epilepsy. It seems that in his hands large doses acted much better than when the bromides were given alone. He recommends \mathfrak{z} ij per diem. My own experience, which I detailed some years ago, was to the effect that it possessed no virtues whatever in ordinary doses. The solution is so difficult to take, and so disagreeable in every way, that many patients prefer almost any other treatment. It cannot be doubted that some cases of epilepsy are benefited by a change of treatment, no matter what, and possibly Wood's cases belong to this class.

Belladonna and ergot are remedies that have had many advocates, Trousseau being the most pronounced champion of the former. Their use in the lighter attacks is attended sometimes by the most happy results, but they cannot be said to have any permanent effect. The first is advantageous because of its power to diminish reflex excitement, and in those undeveloped infantile convulsions which are often grouped under the head of eclampsia its virtues are decided. Belladonna or its alkaloid may be given in combination with the bromides. Ergot or ergotin, in spite of its undeservedly bad reputation, may be given in large doses, one to two drachms of the tincture thrice daily, or five grains of the aqueous extract in the course of the day. Of chloral there is not much to be said. At one time it was thought to possess great virtues, especially in combination with the bromides, but subsequent experience has taught me that its use has many drawbacks, and only in exceptional cases is it to be recommended—viz. in those in which there is a disposition to excitement—either as a substitute for the attack or as a sequel.

³ *Centralblatt für Nervenhilfunde, Psychiatrie, etc.*, No. 18, 1884.

⁴ *Med. News*, Feb. 23, 1884.

The use of the iodide of potassium in combination with the bromides is of great service in symptomatic epilepsies or those of syphilitic origin. The iodide should be pushed, so that the patient may take three or four drachms daily, and its injurious gastric action and unpleasant taste may be done away with by administering it in large quantities of milk or some mild alkaline water, such as Vichy. Among the other remedies used and advocated by various writers are hyoseyamine, the salts of zinc, chloral, the ammonio-sulphate of copper, picrotoxin, strychnine, curare,—all of which have little or no effect in permanently changing the course of the disease. Cerebral galvanism, if properly employed, is certainly worthy of a trial as an adjuvant.

As abortants we may resort to diffusible stimulants—ammonia, alcohol, or some carminative. If the aura be perceived, a drachm of the aromatic spirits of ammonia or a glass of sherry will often prevent subsequent developments, and the inhalation of ten or fifteen drops of nitrite of amyl will avert the attack. Nitrite of amyl may be conveniently used in the form of pearls, which may be first crushed in the handkerchief. The nitrite of soda, which has been recommended as a substitute, is an unstable and dangerous drug, and is not to be recommended.

I called attention some years ago to the virtues of nitro-glycerin as an abortant in epilepsy. It may be given in alcoholic solution or tablets from $\frac{1}{50}$ — $\frac{1}{25}$ of a grain at a dose, to be perhaps repeated. Great care should be taken to procure a reliable preparation.

When a sensory aura proceeds from a particular locality in preference, the application of some local form of irritant is strongly recommended. A blister or light touch of the button of the actual cautery will do, and if the point of origin be one of the extremities a circular blister or cauterizing-line, after the method recommended by Buzzard, will be serviceable in the treatment of the case.

Buzzard has observed the fact, in several of his patients who complained of a sensory aura in the biceps, that when an encircling blister was applied just above this spot the attacks were aborted. In more than one of his cases of partial epilepsy the extraordinary result of a transfer of the convulsion to the other extremity is noted. He found that the circle should be complete, for a blister which half encircled the arm did no good. I have used the same treatment in cases of writer's cramp with marked benefit.

Brown-Séquard has pointed out the good effects of forcible and painful extension of one finger or toe if the aura is of sufficient duration to enable the individual to resort to this procedure.

The condition known as the status epilepticus is best treated by amyl nitrite, which can be administered frequently. Repeated doses of nitro-glycerin, so that its full effects are produced, do more good than chloroform or any of the well-known anæsthetics.

Of setons I have very little to say. At best, they are a barbarous and painful mode of treatment, and, although cures have been effected, I have never been much encouraged by their so-called influence.

Certain intractable cases are helped by surgical procedure, and trephining has sometimes resulted in a cure. I know of one brilliant result obtained by Leo of this city in an old epileptic, in which the use of the instrument over the occipital region resulted in a complete removal of

the disease. It is especially recommended in cases in which the form of the attacks bears some relation to the probable disturbance of the cortical motor-centres; and even in such cases there must be constancy in the method of expression of the convulsion. So often do we find meningeal thickening of an extensive district that it is manifest that trephining would do little or no good. The statistics of the operation are unsatisfactory, for in the large mass of testimony there is great want of exactness as to the pathological suggestions of the attack, and a great deal about the method of procedure and recovery from the operation itself, and very little about the phenomena of the disease.

The diet of the epileptic should be of the most simple kind. Merson,¹ whose carefully-prepared paper is full of valuable statistics, is strongly in favor of vegetable diet, and his results are encouraging. I am convinced that many children never would have become hysterical or epileptic but for injudicious indulgence in animal food. Whenever possible, I confine my patient to a diet of fish, poultry, and fresh vegetables, with fruit. As an exciting cause the overloading of the stomach has so often precipitated attacks as to lead Paget and others to invent the term gastric epilepsy for this form of the disease. The greatest care must be paid not only to diet, but to the general habits of the patient—over-exercise, especially after eating, the avoidance of hot places and high altitudes. A residence by the seashore is preferable to mountainous places; and excitement, over-study, and all agencies favoring cerebral congestion are to be avoided.

THE NEURAL DISORDERS OF WRITERS AND ARTISANS.

BY MORRIS J. LEWIS, M. D.

DEFINITION.—These neural disorders consist of a certain train of nervous symptoms, such as spasm, paralysis, pain, tremor, vaso-motor disturbances, etc., either alone or in more or less complicated combinations, which follow certain muscular acts and are occasionally accompanied by a marked condition of general nervousness; they occur in many of the occupations of every-day life that require for their performance a constant muscular strain combined with more or less delicate movements of co-ordination continued for long periods at a time.

SYNONYMS.—Among the terms used to designate the various forms of the affections produced in the manner just stated may be mentioned the following:

Special Terms.—Writers' cramp, Scriveners' palsy, Steel-pen palsy, Chorea scriptorum, Paralysis notariorum, Graphospasmus, Mogigraphia, Crampe des écrivains, Nevrose des écrivains, Schreibekrampf, Le mal télégraphique, Crampe télégraphique, Klavierkrampf, Pianists' cramp, Tailors' cramp, Loss of grip, etc.

General Terms.—Professional dyscinesia, Professional impotence, Ana-peiratic paralysis, Nevrose co-ordinatrice des professions, Functional spasm, Fatigue diseases, Professional hyperkineses, etc.

None of these terms are satisfactory, and, in fact, it is difficult to find one that will include the various symptoms arising from the habitual use of a muscle or group of muscles, in the same way for long periods at a time, in the different occupations known to give rise to these neuroses, without including diseases belonging to entirely different classes.

It is with some hesitation that I suggest the term copodycnesia (κόπος, toil, weariness, fatigue; and δύσκινησις—δύς, faulty, difficult, hard, and κίνησις, motion, movement) as signifying difficult or faulty motion due to constant repetition of the same act.

HISTORY.—Some of these neuroses have been recognized for years; this is particularly true of writers' cramp, the earliest notice of which I have been able to discover is in a small work by Ramazini,¹ printed in 1746.

Most of the articles upon this subject have been written during the last fifteen or twenty years.

¹ Bern. Ramazini, *Treatise on the Diseases of Tradesmen, etc.*, translated by Dr. James, London, 1746.

ETIOLOGY.—Many of our every-day actions, which we perform almost automatically, are the result of months and even years of practice; this is well exemplified in the act of writing. At first each letter is made by a separate and deliberate act of volition, and considerable thought has to be expended upon its formation; but little by little the preponderance of the volitional element decreases, until at last we write with but little consciousness of each separate movement, and the act becomes almost an automatic one, the sentence being conceived and the hand committing it to paper with but little thought of the intermediate muscular acts. In a somewhat analogous manner do we learn to walk, each movement being laborious and requiring much thought for its execution; in addition to this, we must regulate the amount of the movement and keep in abeyance all associated muscular action.

This last is spoken of by Hasse¹ as an important factor in the etiology of these affections. When, however, any one of the various muscles whose integrity is necessary for the automatic performance of any act becomes affected, let the lesion be in the muscle itself or anywhere in the nerve-substance between it and its centre, or in that centre itself in such a way as to hinder its free response to the nervous stimulus, then the will has to be especially directed to the act in order to counteract the effect of the disability, and some other muscle or group of muscles must be substituted in the place of the one incapacitated. That which was previously performed easily and without fatigue now becomes difficult and exhausting.

It will be in place here to consider in detail the action of the muscles concerned in performing one or two of the acts most prolific of the affections under consideration.

The first of these that will be examined is the act of writing.

Generally speaking, the methods of writing may be divided into two: 1st, where the fingers do all the stroke movements, the arm remaining quiescent except for the lateral movement; 2d, where the pen is held steadily by the fingers and the letters formed by the movement of the whole arm. In the latter the muscles of the hand and forearm are used almost entirely for pen-prehension and poising, although there is generally a slight finger movement for the long strokes; the forearm is allowed to rest upon the bellies of the flexor muscles as a sort of movable fulcrum, the pectorales, teres major, and latissimus dorsi, together with the biceps and triceps, being mainly employed in forming the letters.

This last method of writing is the one mostly taught in the public schools at the present day; and as a large number of muscles are brought into play, and as there is a more even division of the work, it is claimed that fatigue is not so soon complained of as in the first or older method.

The act of writing is primarily divisible, according to Poore,² into three acts: 1st, the act of prehension; 2d, the act of moving the pen; 3d, the poising of the forearm and hand. The muscles concerned in the act of prehension are—the first two dorsal interossei, the opponens, abductor, and flexor brevis pollicis, and, to some extent, the flexor longus pollicis and the extensors of the thumb. The adductor should also be included in this enumeration.

¹ *Handbuch der speciellen Pathologie u. Therapie*, "Krankheiten des Nervensystems," 1te A., Bd. iv., 1869.

² G. V. Poore, *Electricity in Medicine and Surgery*, London, 1876.

The muscles employed in the movement of the pen differ somewhat according to the method of writing. In the finger movement Poore enumerates the following muscles as the ones used, viz.: flexor longus pollicis, extensor secundi internodii pollicis, flexor profundus digitorum, extensor communis digitorum, and also, to a lesser degree, the interossei.

In the second method of writing these muscles are comparatively quiet, except in making the letters which extend far above or below the line, while the muscles previously mentioned when describing this method are the ones called into play. The poising of the arm and hand is mainly accomplished by the supinator longus, supinator brevis, and possibly by the extensors of the thumb.

From a study of what has been written it will be seen that there are two classes of muscular actions concerned: 1st, the steady contraction of the muscles that poise the hand and hold the pen; and 2d, the intermittent contractions of the muscles concerned in moving the pen: both of these classes are equally important in the etiology of writers' cramp.

Chronic fatigue of the muscles is undoubtedly, in some cases, a precursor, if not a cause, of copodyscinesia, and, according to Poore,¹ is occasionally the expression of hyperæmia or mild inflammation of a motor nerve. Acute local fatigue has symptoms which are well known to us all after having taken violent exercise, cramp and pain being the two most prominent ones.

Any student who has dissected much has experienced the intense feeling of fatigue in the muscles required to hold the dissecting forceps, particularly when the spring is a little too strong. Much the same thing is noticed when one who has not been accustomed to write much is for some cause compelled to do so; he will probably notice that in a few hours he is exerting a greater amount of muscular force in pen-prehension than usual, and may even find that he is producing a disagreeable feeling in the distal phalanges by the pressure he is using; he will also probably be aware of a burning sensation between the shoulder-blades.

These symptoms are in all probability dependent upon, or are at least coincident with, a hyperæmia of the nerves and spinal cord, and, if persisted in for a long time without proper intervals of rest must sooner or later interfere with the healthy condition of the spinal cord, as well as of the nerves and muscles of the hand and arm.

Poore, while considering the symptoms of fatigue as in large part peripheral in origin, readily admits that they must generally be accompanied by central changes.

The manner of writing and of holding the pen is of considerable influence in the causation of this trouble. Practically, the fluent writer is more apt to contract this affection than he who writes badly, for the latter seldom obtains a position where steady copying is to be done; theoretically the reverse is true if the amount of work in the two cases is the same.

When the pen-holder is allowed to drop below the head of the first metacarpal bone the movements of the fingers are restricted; the middle and fore finger upon one side of the holder and the thumb on the other act upon the principle of the toggle-joint, so well known in mechanics, and,

¹ "Writers' Cramp and Impaired Writing-Power," *Medico-Chirurgical Transactions*, vol. lxi.

as the pen-holder is drawn backward to make a stroke, bind the distal phalanges tightly against the holder: this in a short time causes fatigue and awkwardness in writing; but if the holder is made to cross the proximal extremity of the first phalanx of the fore finger the toggle-joint movement is destroyed.

These remarks apply of necessity more strongly to the finger movements than to the conjoined finger-and-arm movement.

Writing with a pencil is not as liable to bring on fatigue and nervous trouble as pen-writing, this being mainly owing to the fact that with the former no particular angle is required to be maintained between the point and the paper; there is therefore less effort at poising, as the pencil may be rotated at pleasure, while with the pen one angle has to be maintained. The same remarks should apply to the fluid pencils (stylographic and Mackinnon pens) now so universally used; in fact, they have been considered by Putnam¹ as much easier to write with than the pencil, as less weight need be applied upon the tip in order to write.

The idea that these troubles of writers were due to using steel pens, as once thought, is manifestly without foundation, as the affection was recognized before the time of the introduction of steel pens, which was from 1800 to 1820.

Fine sharp pens are, however, more productive of evil than composition pens or those with a broad soft nib, as they do not move as easily over the paper, and therefore introduce a difficulty, although a slight one, in the act of writing. The theory that the chemical action between the ink and the metallic pens, and the friction of the pen on the paper, generate sufficient electricity to affect the fingers through the medium of the metallic portion of the pen-holder is too preposterous to mention, except to show what curious reasons are given in attempting to explain obscure and difficult subjects.

The next occupation which very frequently gives rise to these affections is telegraphy.

The invention of the Morse telegraph in 1844, and its general introduction, both here and abroad, a few years later, has proved a most fertile source of copodyscinesia, although but little has been written on this form of neurosis, Onimus,² Robinson,³ and Fulton⁴ being among the few to describe it, although several later writers mention its existence.

Telegraph operators, particularly those employed in large cities, whose time is nearly all taken up with their work, are more exposed to the causes of copodyscinesia than those following other trades. They are not only exposed to the danger of contracting the affection by using the telegraph-key in transmitting messages, but when not so employed are receiving messages by sound and writing them down, frequently at the rate of thirty to forty, or even more, words per minute. Thirty words a minute is good telegraphy: this would require, on the average, nearly 600 sep-

⁴ Thomas Weymss Fulton, "Telegraphists' Cramp," *Edinburgh Clin. and Path. Journ.*, Feb. 2, 1884.

arate contractions. This would be 36,000 contractions per hour, while to write the same sentences would require about 10,000 less.

The operators employed by the Associated Press, although comparatively few in number, two hundred probably including all in the United States, write for hours at a time, using a stylus and manifold writing-books, making as many as twelve copies at one writing; this obliges them to grasp the stylus very firmly and to press with considerable force, making the act of writing much more difficult.

In addition to the work mentioned above, those who have large numbers of messages to transmit become so expert that to save time they make a record concerning the last message sent with the left hand, while they are telegraphing the next one with the right hand. A complicated act of co-ordination is thus being performed with each hand, the difficulty of which may be appreciated by any one if he but try to perform it.

An editorial in the *London Lancet*¹ states that "telegraphers' cramp will, we have little doubt, take its stand among the last-mentioned curiosities" (milkers' cramp, hammer palsy, etc.), and "that the telegraph clerk usually enjoys repeated intervals of complete rest, and runs consequently hardly any risk."

Hammond² likewise states that telegraphers' cramp is rare in the United States, but a slight investigation proves these two statements to be, unfortunately, very far from the truth. According to recent statistics,³ the Western Union Telegraph Company employs nearly twenty thousand operators, who transmit annually over thirty-five million messages, and as investigation seems to prove that a very large number, if not the majority, sooner or later show some symptoms of copodyscinesia, it becomes evident that this neurosis is far from rare, although hitherto almost entirely overlooked by the medical profession.

Operators are very loath to confess that they are suffering from loss of grip, as they have termed it, for then they are considered as less efficient than formerly, and may be asked to resign in favor of one not affected, or be lowered in their salary—a point of great moment, as telegraphy is their means of support. This accounts for the apparent small number of the cases.

In telegraphing, the knob of the key, a circular disc of hard rubber more than one inch in diameter, and placed about one and a half inches above the level of the table, is grasped, as a rule, between the thumb and middle finger, with the tip of the index finger resting on top, the position being quite analogous to the method of pen-prehension, the strain, although much less, falling on the same muscles, but as all lateral movements of the key are impossible, the muscles employed in poising are not brought into play as in writing. The arm is either allowed to rest upon the table, upon the flexor mass of muscles of the forearm near the elbow as a kind of movable fulcrum, or is held with the forearm parallel to the table and a short distance above it.

The movements of telegraphing are made by the alternate action of the triceps, which depresses the wrist by extending the forearm, assisted by the flexor carpi radialis, flexor carpi ulnaris, flexor sublimis, and flexor

¹ 1875, vol. i. p. 585.

² Wm. A. Hammond, M. D., *Dis. Nervous System*, 6th ed., New York, p. 789.

³ J. B. Abernethy, *Commercial and Railway Telegraphy*, Cleveland, Ohio, 1883, 2d ed.

profundus digitorum on the one hand, and the biceps and supinator longus, which elevate the wrist by flexing the forearm, assisted by the extensor carpi radialis longior, extensor carpi radialis brevior, extensor carpi ulnaris, and extensor communis digitorum on the other.

The movement of the key-knob, being about the one-twenty-fifth of an inch, is so slight that it may be entirely ignored, so that with the fingers upon the key and the forearm resting upon the table near the elbow the motion must be a downward and upward one of the wrist; when, however, the arm is held above the table and parallel to it, the motion is more extended, the shoulder-muscles being used to support the arm.

The wrist is held in a supple manner, and not rigidly, the momentum of the downward movement being used to close the circuit; this, as before stated, is made mainly by the triceps, and is checked by the flexors and supinator longus.

The extensors of the wrist and fingers have a double duty to perform, for, besides assisting in recovering from the downward stroke, they have to support the hand during the whole act of telegraphing, in order to prevent the weight from resting on the key, which would prevent quickness in making and breaking the circuit.

On long circuits, particularly in wet weather, when much electricity escapes from the line, the movements have to be made with much more decision than usual in order to make the signals intelligible at the distant station.

The accompanying diagram shows well the movement of the wrist as above described, the hand and wrist moving into the position of the dotted lines when the downward stroke is made.

FIG. 28.

Our hand is essentially a prehensile organ, and as such causes us to educate the flexors the most; the extensors, being mainly used to relax the grasp of the fingers, are weaker, and the constant strain spoken of above, being thrown upon them, explains the fact that in telegraph operating these are the muscles most frequently attacked by cramp. (See Symptomatology.)

The following figures are of interest as proving the great superiority, in point of strength, of the flexor over the extensor muscles of the wrist and fingers. The measurements were made by the dynamometer of V. Burq, great care being taken to apply the instrument upon corresponding points of the palmar and dorsal surfaces of the hand. The grasp of the average man, which includes all the flexor muscles of the fingers and thumb, equals 125 pounds, while the power of the flexors of the wrist, exclusive of the fingers, equals 40 pounds. In marked contradistinction

to this the extensors of the wrist register 35 pounds, and the extensors of the fingers only 7. The total power of all the flexors is therefore 165 pounds, and that of the extensors 42 pounds, nearly four times less (3.92). In women the ratio is the same, although the number of pounds registered is about half.

From the foregoing enumeration of the muscles used in writing and telegraphing it may be seen that the brunt of the work does not fall on the same muscles in the two acts, so that operators are seen utterly unable to telegraph more than a few words intelligibly who can still write a fluent hand. The two forms of neuroses often coincide in the same subject, as all telegraphers are of necessity scribes; in fact, the majority suffer from both forms, and as a rule the most difficulty is experienced in telegraphing, and not in writing, although the reverse is frequently seen. But rarely does one see an operator who, unaffected as far as telegraphing is concerned, has difficulty in writing on account of this curious neurosis.

Of the muscles enumerated in the foregoing discussion, six are supplied, either wholly or in part, by the ulnar nerve—namely, the first two interossei, adductor pollicis, flexor brevis pollicis (inner half), flexor carpi ulnaris, and flexor profundus digitorum (inner part); and seven by the median nerve wholly or in part—namely, the opponens and abductor pollicis, flexor brevis pollicis (outer half), flexor longus pollicis, flexor profundus digitorum (outer part), flexor carpi radialis, and flexor sublimis digitorum.

The remaining important muscles are supplied by the musculo-spiral and its branches, except the biceps, which is supplied by the musculo-cutaneous.

The ulnar nerve supplies fifteen of the muscles of the hand; many of these are not prominently brought forward in writing, but are more or less used in keeping the hand in the required position.

Poore, after a careful study of 32 cases of undoubted writers' cramp, found the muscles affected in the following proportions:

| | | |
|---|-------------------------------|---------------------|
| Interossei | (supplied by the ulnar nerve) | 18 times. |
| Extensors of the thumb | { " " " musculo-spiral) | . . . 10 " |
| Flexor brevis pollicis | { " " " median and ulnar) | . . . 7 " |
| Abductor " | { " " " median) | 7 " |
| Flexor longus " | { " " " ") | 4 " |
| Adductor " | { " " " ulnar) | 3 " |
| Opponens " | { " " " median) | 2 " |
| All the muscles of the forearm, more or less, | | 2 " |

—showing that the muscles supplied by the ulnar nerve were affected more often than those supplied by the others.

The musculo-spiral and its branches supply the extensors of the thumb, fingers, and wrist, besides the two supinators; and by referring to the muscles most called into action in the act of telegraphing it will be seen that the majority are supplied by this nerve and by the median, which supplies the majority of the flexors. This statement explains to a great extent the fact that telegraph operators may be unable to telegraph and yet be able to write, as the muscles most important in the two acts have not the same nerve-supply.

The integrity of these nerves is therefore of the first importance in all

cases requiring the use of the fingers and forearm, and many cases of copodyscinesia undoubtedly have a subacute inflammation of these nerves, or at least a congestion of the same, as their foundation, the neuritis or congestion being overlooked, owing to its mild type.

S. Weir Mitchell¹ states that subacute neuritis is often incapable of distinct clinical discrimination when of a mild type and when there is an absence of traumatic cause. Mills² states that "a lesion of the sensitive fibres profoundly affecting this power of conducting impressions may not cause pain, and that pain is not a necessary symptom of inflammation of a mixed nerve: this is an important fact, as I think too much stress is often laid on pain as a symptom of neuritis, leading to error in diagnosis and treatment."

Other Forms of Copodyscinesia.—In violin-playing the bow is held steadily between the fingers and thumb for long periods at a time, and the left arm is forcibly held in supination in order to bring the fingers upon the strings—actions well calculated to cause trouble if persisted in, not taking into account the rapid movements of the fingers which are necessitated in playing and the movements of the arm in bowing. The violinist is therefore liable to suffer in both arms, but in a different manner in each, as different muscles are used in bowing and in fingering.

The other musical instruments necessitating great education in the movements of the fingers and wrist are also liable to cause these neuroses, but this is not true of those wind instruments which require education of the movements of the lips and tongue. Piano-playing is a frequent cause of these troubles, which have been known to appear quite suddenly during the practising of some difficult piece.

In fact, all occupations which require a muscle or a group of muscles to be kept in a constant more or less firm contraction, together with fine movements of co-ordination in themselves and in the neighboring muscles, may be expected to furnish cases of this class of disease; the muscles affected necessarily varying with the work done, mere routine work being more liable to cause trouble than that which is new and original, as in the latter case time has to be taken to elaborate it, thus giving temporary rest to the muscles.

Besides the forms already mentioned these neuroses have been known to effect compositors, engravers; seamstresses, tailors, from using the needle or scissors; cobblers; bricklayers, from using the trowel; artificial-flower makers; weavers; milkers; painters; dentists; ballet-dancers, from standing on their toes; blacksmiths and those using the hammer; carpenters, from using the saw and screw-driver; electrical-instrument makers, from winding coils; turners; watchmakers; fencing-masters; cigar-makers; makers of photographers' gelatin plates; knitters and those using the crochet-needle; billiard-players; counters of money; dressers of hides; pedestrians; and a few others.

Writers, telegraph operators, and musicians are those which by far are the most frequently affected, the others being almost curiosities. Among the latter may be mentioned the case, recently coming under my notice, of pain in the right forefinger and arm, with cramp in the former, upon

¹ *Injuries of Nerves, and their Consequences*, by S. Weir Mitchell, M. D., Philada., 1872.

² F. T. Mills, M. D., "On Two Cases of Neuritis of the Ulnar Nerve," *Maryland Med. Journ.*, vol. viii. p. 193, 1881.

any prolonged attempt to read with this finger the raised letters of the alphabet of the blind. The patient was a blind woman depending for her living upon crocheting, which occupation was also seriously interfered with by this trouble.

After inquiring, in factories, etc., I find that the disease is by no means a recognized one among the workmen. Among telegraphers, however, it is so well known that they have called it the loss of grip, while in France it is known among them as *le mal télégraphique*.

Gardner,¹ after a careful investigation, finds no proof that physical disease originates in, or is even aggravated by, the use of the sewing-machine, and he has "never even heard of a case of cramp." He comes to this conclusion after having visited many large factories where sewing-machines are used and worked by foot-power; his remarks apply to those machines where the feet are worked together, and not alternately, which last has been known, according to Down,² to cause serious troubles, of an entirely different kind, however, from the one under consideration, and with which this subject has nothing in common.

PREDISPOSING CAUSES.—Tobacco and Alcohol.—Both of these articles exert a powerful effect upon the nervous system, tobacco particularly being a factor in the causation of many cases of neurasthenia. The first effect of tobacco and alcohol in small doses on the brain and spinal cord is, according to Boehm and Von Boeck,³ that of an excitant; subsequently it acts as a depressant. Eulenburg⁴ mentions tremor as of very frequent occurrence, and states that he has frequently noticed it in young cigar-makers who smoke to excess.

Cigarettes are more injurious than other forms of tobacco used in smoking, as the smoke is nearly always inhaled, a greater effect being thus produced by a given amount of the drug. Besides this, cigarettes contain a large amount of other substances deleterious in their effects. Trembling of the fingers and hand is frequently seen in those smoking cigarettes freely.

The majority of the cases of copodyscinesia that are in the habit of using either of these articles acknowledge that their use increases their disability; in very exceptional cases the moderate use of tobacco appears to soothe and quiet, and thus relieve some of the symptoms.

Age.—Copodyscinesia is a disease of early adult life; it is rare in old age. In 39 out of 43 cases of telegraphers' cramp coming under my notice the age of the patient at the outset of the disorder could be accurately determined. The average was 23.94 years. The average age of all cases of the various forms of copodyscinesia seen by me up to the present time (1886) is 25.96 years.

Sex.—The influence of sex as a predisposing cause of these affections has not been studied with sufficient care, although a few authors allude to it.

Onimus⁵ states that women are more frequently affected than men with telegraphers' cramp. Erb⁶ states that writers' spasm is met with more

¹ A. K. Gardner, M. D., "Hygiene of the Sewing-Machine," *Am. Med. Times*, Dec. 15-29, 1860.

² "Hygiene of the Sewing-Machine," *London Lancet*, 1866, vol. ii. p. 447.

³ *Ziemssen's Cyclopædia*, Amer. ed., vol. xvii.

⁴ *Ibid.*, vol. xiv.

⁵ *Loc. cit.*

⁶ "Writers' Cramp and Allied Affections," *Ziemssen's Cycl.*, Amer. ed., vol. xi.

frequently in men, much more rarely in women, and that pianoforte-players' spasm occurs more frequently in women, and particularly in neuropathic persons who belong to nervous families. Hasse¹ and Romberg² consider that writers' cramp especially occurs in men, women being affected very rarely. Of the 75 cases of impaired writing-power reported by Poore,³ only 17 were women, while of the 31 cases of undoubted writers' cramp included in the 75, all were men.

It may be seen that the male sex has been employed far more frequently than the female in most of the occupations previously mentioned, so that a larger percentage of men would naturally be affected; but now that women are being employed more generally a larger number of the female sex may be expected to suffer in this way.

Whether sex, per se, has much influence as a predisposing cause is difficult to say, as statistics are wanting, but it is probable that with the same amount of work given to each sex a large proportion would be found among women.

Women are being employed to a considerable extent in telegraphy, and although I have been able to collect but 4 cases of this form of copodyscinia affecting women out of a total of 43, I have reason to believe it is quite common among them, my mode of collecting statistics (soliciting replies to printed questions) being much more likely to give a larger percentage of answers from men.

Hereditary Influence and Nervous Temperament.—Both of these factors seem to play an important rôle as predisposing causes to these affections. Cases are on record where several members of the same family were the subjects of writers' cramp. The statement made by Erb (*vide supra*), that neuropathic persons and those who belong to nervous families are more subject to these affections than others, seems to me to be true, at least to a great extent, for a careful inquiry into the history of cases coming under my knowledge has quite often elicited the statement that migraine, functional spasm, epilepsy, hay fever, neuralgia, writers' cramp, telegraphers' cramp, or general neurasthenia has existed either in the immediate family or in the patients themselves. Hasse⁴ is also of the same opinion.

Whittaker⁵ states that many of the cases coming under his notice, if not the majority, occurred in individuals of irritable nervous temperament, subject themselves to, or the descendants of parents afflicted with, migraine, chorea, epilepsy, paralysis, or some form or other of neurosis, but that a certain contingent of the minority of cases occurred independently of any neurosis or any abuse of alcohol or sexual excess.

Fritz,⁶ after studying 25 cases of writers' cramp, found 7 who either stuttered, squinted, or had choreoid movements or œsophageal spasm at the same time; but it is probable that a few of these cases at least were due to some central lesion (post-paralytic chorea?).

Beard⁷ holds an opinion directly the reverse of the vast majority of the authorities upon this subject, and states that this disease occurs mostly in

¹ *Loc. cit.*

² *Nervous Diseases*, vol. i. p. 320.

³ *Loc. cit.*

⁴ *Loc. cit.*

⁵ *Cincinnati Lancet and Clinic*, N. S., vol. iv. p. 496, 1880.

⁶ "Ueber Reflexionsfingerkrampf," *Oesterr. Jahrb.*, März u. April, 1844, quoted by Hasse, *loc. cit.*

⁷ G. M. Beard, M. D., *loc. cit.*

those who are of strong—frequently of very strong—constitution, and that it is quite rare in the nervous and delicate; and when it does occur in those who are nervous it is easier relieved and cured than when it occurs in the strong.

That in the majority of the cases there is an emotional factor is evident to every one who has seen a considerable number, the knowledge that some one is looking on and will notice the disability being almost sure to aggravate the symptoms. This is frequently noticed among telegraph operators, and is well exemplified in the following answer made by a female operator: "If I am working with a disagreeable or fault-finding operator, who I know will make unpleasant remarks about my sending, and break me (break the circuit) on certain difficult letters, it is almost impossible to make those letters correctly with either hand." Again she says, "If I come to the difficult letters without thinking about them, I can make them much easier than if I look ahead in the message and see them; for instance, some time after I had ceased using my right hand on account of the cramp, an outside occurrence made me very angry; just then a message was placed on my desk, and with my mind fully occupied with my grievance I sent the message with my right hand very easily and quickly."

Wasting Diseases.—These favor the production of these affections in those predisposed to them by occupation or otherwise, by the constant drain upon the system. Numbness of the fingers and stiffness are occasional symptoms of renal disease, and would naturally aggravate any difficulty of writing and so-forth that the patient might have. Mitchell¹ reports two cases of writers' cramp dependent upon or coincident with albuminuria, which were treated in vain until the condition of the kidneys was discovered: under appropriate treatment for this condition one recovered entirely from the cramp and the other improved greatly.

Traumatism, etc.—Injuries, etc. occasionally act as predisposing causes; thus cases are on record where the starting-point seemed to have been an ingrowing thumb-nail, and others where it was the pressure of large sleeve-buttons upon the ulnar nerve; and tight sleeves seem to have been the starting-point of inflammatory troubles ending in writers' cramp. An inflammation of the periosteum of the external condyle (node) and a painful ulcer upon the forearm are reported by Runge² as giving rise to symptoms closely allied to this affection. Seeligmüller³ mentions a case where the symptoms came on after an insignificant grazing bullet-wound of the knuckle of one of the fingers.

SYMPTOMATOLOGY.—Owing to the fact that various causes give rise to these affections, and that the different groups of muscles implicated differ with the varying occupations of those suffering, no one stereotyped set of symptoms can be described as applicable to each case, and no one symptom can be looked upon as diagnostic.

The symptoms most frequently seen may be classified under five heads—viz.: I. Cramp or spasm; II. Paresis or paralysis; III. Tremor; IV.

¹ S. Weir Mitchell, M. D., "Nervous Accidents in Albuminuria," *Philada. Med. Times*, Aug. 1, 1874, p. 691.

² "Zur Genese u. Behandlung des Schreibkrampfes," *Berl. klin. Wochenschr.*, x. 21, 1873.

Pain or some modification of normal sensation; V. Vaso-motor and trophic disturbances.

These may, and generally do, exist in various combinations, and they may be accompanied by other symptoms of nervousness; they are not of necessity confined to the hand or arm, but may become more or less general. At first they are usually only seen after long continuance of the occupation which produced them, but later any attempt to perform this act will cause their appearance, although it may not be noticed in any other of the daily avocations.

In some of the rarer cases the neurosis makes its appearance suddenly after a prolonged siege of work. It has been generally stated that writers' cramp, for instance, only manifests itself on attempting to write, but this is due to the fact that there is no other occupation which exactly needs the same co-ordination of the muscles, for others can be substituted in the place of those affected. This is particularly seen in the early history of the cases, but when it has become pronounced in character any analogous movement, such as holding a spoon or fork or paint-brush, will be sufficient to produce it. Difficulty in buttoning the clothes with the fore finger and thumb is frequently noticed.

I. Cramp or Spasm (Spastic Form).—The first form of this disease to be considered is that in which cramp or spasm is present. This is one of the most frequent symptoms, and when present usually attracts the most attention. In most of the articles written upon these affections great importance has been given to this symptom, which, however, may be absent during the whole history of the case, but when it does appear it usually indicates an advanced stage. The term writers' cramp is an evidence of the widespread opinion of the importance of this symptom.

The cases that present themselves to the physician have usually been affected for some time, and where cramp is present an earlier examination would probably have resulted in the discovery of premonitory signs before the appearance of the spasm or cramp; and in fact it may be stated that this symptom is always preceded, or at least accompanied, by one or two more. The muscular contraction may be so slight as to amount to a mere occasional awkwardness, in writers' cramp an abnormal grasp of the pen-holder being all that is noticed; or it may be so severe as to cause a tonic contraction of the muscles affected, which may continue for some time after the exciting cause has been removed, as in the cases reported by Poore¹ and S. Weir Mitchell.²

As might be supposed, these spasms affect most usually the upper extremities, although they may affect the lower, as is occasionally seen in workers on the lathe and in pedestrians. Other muscles than those necessary to perform the act that has become difficult may also be seized with spasm coinstantaneous with the spasm of the affected part; thus the left arm may be the seat of associated movements while the right is being used: these are, however, most frequently seen in the affected arm when the other is being used to relieve it; they may also be noticed in the legs, although much more rarely.

Gallard³ reports a case of a street-pavior who had associated spasm of

¹ *Electricity in Medicine and Surgery*, London, 1876, p. 209.

² "Functional Spasm," *Amer. Journ. Med. Sciences*, Oct., 1876, pp. 322, 323.

³ "Crampe des Écrivains," *Progrès médical*, v., 1877, p. 505.

both sterno-cleido-mastoid muscles, which came on only when using the instrument to settle the stones. Dally¹ reports a case of a woman who had spasm of the left sterno-cleido-mastoid muscle at the time the right hand was seized with cramp in writing. More rarely all the muscles on one side of the body may be affected. Reynolds² reports such a case.

In the spastic form of the disease an early investigation usually shows a rigidity or spasm of one or more of the fingers, coming on when an attempt is made to perform the act which originated the trouble, and occasionally only on performing that act; but this statement, so strongly insisted upon by some authors as a diagnostic symptom, does not universally obtain.

The contraction may affect either the extensors or the flexors; in the former case—in writing, for instance—the pen can with difficulty be kept upon the paper, and the stroke movement is interfered with; if the spasm is of the flexors, which is of the most common occurrence, it usually affects the fore finger and thumb; the pen is then forced downward, and upon attempting to make the upward movement catches in the paper; besides, there may be with this a flexion and adduction of the thumb, which causes the pen-holder or pencil to be twisted from the grasp, occasionally with sufficient force to throw it to some distance. The other fingers may be similarly affected. The supinator longus is quite a common seat of spasm, the pen being thereby drawn from the paper by a partial supination of the forearm.

Sometimes the character of the spasm cannot be described, the hand seeming to run away with the pen.

The patient who feels these spasms or contractions coming on soon changes the manner of holding the pen-holder, so as to relieve the affected muscles and to use those which are but slightly or not at all affected. Many grotesque manners of writing may thus be encountered. One sometimes employed by those seriously affected is to grasp the holder in the closed hand, holding it nearly at a right angle to the forearm, all movements being made with the whole arm, thus relieving the finger-muscles. The diagram on p. 457 shows the method of writing adopted by a patient who has a marked spasm of the flexors of the fingers and thumb, preventing his writing in the ordinary manner; he is also the subject of telegraphers' cramp.

These means, however, give but temporary relief, as, sooner or later, if writing is persisted in, the muscles of the arm and shoulder become implicated.

In telegraphers the extensors of the wrist are frequently affected, so that the operator is unable on account of the spasm to depress the key of the instrument with sufficient force to close the circuit, the signals being made, so to speak, in the air, or else a dot (.) is made in place of a dash (—). The extensor spasm seems to be the most frequent form of the cramp among telegraphers, many of them saying that they are unable to keep their fingers upon the key-knob. It will generally be found that the characters that are the most difficult to make are those which are composed entirely of dots, such as *h* (....), *p* (.....), *6* (.....), or those end-

¹ "Traitement des Spasmes professionnels," *Journ. de Thérapeutique*, No. 3, 10 Février, 1882.

² *System of Medicine*, "Writers' Cramp," vol. ii. p. 287.

ing with dots, such as *b* (—...), *d* (—...), *8* (—....). Some of the spaced characters are also difficult to make, such as *z* (... .), *&* (. ...), *y* (.. ..).

Occasionally one finger will become rigidly extended during telegraphing, and any attempt to prevent this will bring on great discomfort and greater disability. When, more rarely, it is the flexors which are affected, the key is depressed with undue force at the wrong time, and a dash is made

FIG. 29.

where a dot was intended, or an extra dot or so introduced, or the proper spacing of the characters prevented, thus rendering the message unintelligible.

The telegraph operators who experience the most difficulty in transmitting usually have a cramp of the extensors, and those having the most difficulty in receiving (writing) usually have a cramp of the flexors, although the reverse is occasionally seen.

In some cases of the spastic form of copodyscinesia the contraction almost becomes tetany; thus there may be a contraction of the flexors of the wrist, which comes on whenever any attempt is made to use the hand, although the fingers may be entirely unaffected, or there may be a more or less constant contraction, greatly exaggerated on any attempt at motion.

Lock-spasm, as described by Mitchell,¹ is a rare form of this affection: in this the fingers or hand become locked, so to speak, in a strong contraction, even stronger than the patient could ordinarily produce by an effort of will; this lasts for a considerable time, and after its disappearance the customary work may be resumed. Duchenne² likewise reports some curious cases of functional spasm analogous to the foregoing.

¹ *Loc. cit.*

² Duchenne (de Boulogne), "Note sur le Spasm fonctionnel, etc.," *Bull. de Thérap.*, 1860, pp. 146-150.

II. Paresis or Paralysis (Paretic Form).—More or less weakness of some of the muscles of the hand or arm is frequently seen in cases of copodyscinesia; this is, however, less common than the spastic form, and, like the latter, is preceded or accompanied by other symptoms. This form occasionally follows the spastic, or it is seen in those cases where the cause of the trouble has been a preceding neuritis, or it may be due to professional muscular atrophy as described by Onimus,¹ where, contrary to the ordinary rule, excessive use of a muscle or set of muscles produces, instead of hypertrophy, a condition of considerable atrophy, usually of the larger muscles first, which is preceded for some time by pain and cramp in the affected parts, with fibrillary twitchings; this is amendable rather rapidly under appropriate treatment, and thus differs from progressive muscular atrophy, with which it is apt to be confounded.

Some of the cases of this group may be confounded with those of the former, as there may be an apparent cramp or spasm of the unopposed healthy muscles. Zuradelli² considers this condition to be the one ordinarily found in this disease.

A paretic condition of one muscle may coincide with a spastic condition of another not its opponent, the paralyzed muscle being the one first affected.

When a patient with paresis or paralysis as the most prominent symptom attempts to write, an intense feeling of fatigue usually appears, and the writing becomes difficult or impossible—not from a too ready response and spasm, but from an inability of the muscles to obey the will; the pen-holder is held in a feeble manner, and sometimes falls from the grasp. There may be a sense of utter weakness and powerlessness, the arm feeling as if glued to the table.

Duchenne³ calls attention to this form of trouble, which he styles *paralysie fonctionelle*, and states that it is much less common than functional spasm.

New methods of holding the pen are as constant in this form as in the spastic, as it is as necessary in one as in the other to avoid as much as possible the use of the affected muscles. A carpet-weaver, seen by myself, was obliged to tie the knots in the warp on the distal extremity of the second phalanx of the thumb, as the extensor secundi internodii pollicis was partially paralyzed, so that he was unable to keep the distal phalanx extended. This condition came on when he was a compositor, and compelled him to change his trade. A condition of spasm had preceded the paralysis.

The first dorsal interosseus muscle is frequently the seat of paresis; this is readily discovered by measuring the power which the patient has of lateral movement of the index finger and comparing it with that of the sound hand.

III. Tremor (Tremulous Form).—Trembling or unsteadiness of the fingers is occasionally seen, usually most marked in the fore finger when the hand is at rest with the fingers slightly separated. In some cases this may be sufficient to cause unsteadiness in work, prolonged work and over-fatigue being most apt to produce it; as previously mentioned, this is one of the premonitory symptoms of professional muscular atrophy.

¹ E. Onimus, "On Professional Muscular Atrophy," *Lond. Lancet*, Jan. 22, 1876.

² Crisanto Zuradelli, *Gaz. Med. Ital. Lomb.*, Nos. 36-42, 1857; also *Ann. Universali*, 1864.

³ *Loc. cit.*

An oscillatory trembling, due to implication of the supinators and pronator, is described by Cazenave,¹ which interfered greatly with the act of writing. Tremor is of itself rarely complained of by those affected with copodyscinesia, unless it becomes sufficiently marked to cause interference with work.

A peculiar form of nystagmus occasionally seen in miners may be considered as belonging to this category. According to Nieden of Bochum² it is caused by eye-strain in the defective illumination of the mines, and consists not of a spasm, but of a defective innervation, like the tremor of old persons. C. B. Taylor³ of Nottingham and Simeon Snell⁴ also speak of this as a fatigue disease.

IV. Pain, or Some Modification of Normal Sensation.—Every case of copodyscinesia, without exception, has at one period or another of the disease some modification of normal sensation in the hand or arm. Usually the very first symptom that attracts the patient's attention is a sense of fatigue or tire in the hand or arm, which at first appears only after a considerable amount of work; if rest is taken now, the part regains its normal condition, but if the work is continued the sensation increases, and the amount of labor necessary to cause the disability gradually grows less and less until any attempt suffices to produce it. A painful sensation or a sense of heat may be experienced in the shoulders or in the cervical or upper dorsal spine at the time the foregoing symptoms are felt.

These symptoms are due to chronic fatigue in many instances, this being an important factor in the causation of these troubles. An expression frequently used by those affected is that the hand or arm becomes lame; this sense of tire may be slight or may be of an intense aching character, almost unendurable.

Should spasm supervene, then there will be a sense of tension and pain in the rigid bellies of the muscles. When a subacute neuritis is present, as frequently occurs, all the symptoms common to that condition appear—viz. pain over the various nerve-trunks and at the points of emergence of their branches, either spontaneous or only solicited on pressure; areas of hyperæsthesia or anæsthesia; a sense of itching or tingling or pricking in the arm or hand; or a sense of numbness, causing the part to fall asleep.

As previously mentioned under Etiology, pain may be absent in some cases of subacute neuritis. Occasionally, the distal phalanx of the fore finger or thumb becomes exquisitely sensitive to pressure, and there may be a burning or stinging pain under the nail, severe enough to make the patient think local suppuration is about to take place.

Sensory disturbances in the region of the hand supplied by the radial nerve are quite common, less so in the region supplied by the median, and least of all in the ulnar distribution. This last having never been seen by Poore, although, as pointed out by him, the muscles supplied by the nerve are those most frequently implicated in this disease when it affects scribes, his explanation is that the deep motor branches are

¹ "Observations de Tremblements oscillatoires de la Main Droite," *Gaz. méd. de Paris*, 1872, pp. 212-215.

² "The Pathogenesis and Etiology of Nystagmus of Miners," *Am. Journ. Med. Sci.*, Oct., 1881.

³ Quoted by Poore, *loc. cit.*

⁴ "Miners' Nystagmus," *Brit. Med. Journ.*, vol. ii., 1884, p. 121.

widely separated from the sensory branches of the nerve, while this is not true of the radial.

One case of impaired sensation affecting the ulnar distribution, and consisting of slight numbness of the palmar surfaces of the ring and little fingers, has come under my observation. The patient was a young woman affected with pianists' cramp, having as its foundation a subacute neuritis of the musculo-spiral and ulnar nerves; the trouble had lasted five years.

A curious form of pain, as of a bar thrust diagonally through the hand, has been complained of; again, the arm, hand, or fingers may be the seat of a subjective sensation of weight, so that one arm will feel very much heavier than its fellow, or the hand may feel as heavy as lead. A soreness and sense of tightness, as of a band around the wrist, a throbbing and pulsation, or a tense feeling as if the skin would burst when the hand was closed, have been noticed occasionally.

V. Vaso-motor and Trophic Disturbances.—Among the rarer symptoms seen are vaso-motor and nutritional changes; these never occur alone, but are accompanied by cramp and fatigue or by some evidence of nerve-lesion.

When a patient with this symptom attempts to perform the task which produces the disability, in addition to the fatigue, spasm, or pain the veins on the back of the hand and fingers will be seen to slowly enlarge; this may gradually increase until it extends over the whole arm, the parts becoming more or less turgid with blood, the temperature at the same time being somewhat increased. A marked sensation of throbbing accompanies these symptoms.

Other parts more distant may become affected, the face becoming flushed, palpitation of the heart and profuse perspiration, either local or more or less general, ensuing, followed by exhaustion.

When there is a marked hyperæsthesia of the distal phalanges of the fingers, there may be a glossy appearance of the skin, or the parts may appear inflamed and as if about to suppurate, or there may be chilblains. A rare symptom is change in the character of the nails, which become brittle and crack off like shell, either spontaneously or when an attempt is made to cut them.

GENERAL SYMPTOMS.—Besides the various symptoms above enumerated, there may be others more general in character, such as intense headache and great general nervousness, the emotional character being generally well marked, as is shown by the disability being greatly increased when the patient knows some one is watching and criticising. There may be also vertigo and sleeplessness. When there is an associated spasm of the analogous muscles of the other arm and hand, although there is no apparent trouble in the arm which is being used, it shows that the hitherto almost automatic act is losing some of its automatism: this, although rare, is an important premonitory symptom.

A rare symptom, which, as far as my knowledge allows me to say, is confined to telegraph operators, is an inability to mentally grasp the proper number of dots and dashes composing certain Morse characters: this usually coincides with the difficulty experienced in making those characters after they have been thought of, and also makes it difficult for them to recognize them by sound even when properly made by another

person. The characters composed entirely of dots seem to cause the most trouble in this way.

Electrical Reactions.—In those cases where spasm of one or more muscles is a more or less marked symptom electrical examination shows, both to the faradic and galvanic current, a quantitative increase in the reaction, both in the nerves and muscles; with the galvanic current the cathodal closing contraction is more marked than the anodal closing contraction, as in health ($KaSZ > AnSZ$); only this formula is most marked in the affected arm. When paresis is present there will be a quantitative decrease in the reaction, the formula still being $KaSZ > AnSZ$. In the same arm some muscles may show a quantitative increase and others a quantitative decrease. Where there is a neuritis present the electrical examination will show a quantitative increase, but where the disease has advanced to degeneration of the nerve the reaction of degeneration will be found, and the formula will be $AnSZ > KaSZ$; there is, therefore, a qualitative change, but this must be looked upon as rather uncommon in this class of diseases.

Poore¹ is of the opinion that increased irritability shows an early, and decreased irritability a late, stage of the same condition. According to his tables, but very few of his 75 cases of impaired writing-power showed this quantitative increase, while every case showing the least evidence of cramp that has come under my observation has shown it in one or more muscles; in a few cases the antagonistic muscles showed a decrease. Increased sensitiveness to both currents is sometimes noticed.

COURSE.—The course of the disability is slow and, unless appropriate treatment is instituted, progressive, although at times there are periods during which the symptoms ameliorate without assignable cause, thus giving rise to false hopes. The usual history is that group after group of muscles becomes implicated as these are in turn used to relieve those first affected, the left arm, should this be used, becoming disabled in the same manner as the right, and the unfortunate sufferer is then compelled to give up his calling or else to lessen very materially the amount of his labor.

DURATION.—As might be inferred from what has been written, those who have suffered for years with this affection may expect it to continue for the remainder of their days; but the later investigations upon this subject give rise to much hope that in future the duration of this troublesome complaint will be materially shortened when the disease is recognized early and treatment instituted at the very first symptom.

DIFFERENTIAL DIAGNOSIS.—Although many of the cases of copodyscinesia are diagnosed with comparative ease, there are others which require much study, as there are several disorders which are apt to mislead by the similarity of symptoms.

Any affection of the finger-joints or of the muscles of the hand or arm, or any disease of the nerves or of the spinal cord, from which these nerves arise, or of the corresponding part of the brain, will necessarily interfere more or less with the finer movements of the hand, and yet all these, manifestly, cannot be considered cases of this affection.

Where the symptoms are undoubtedly caused by over-use of a part, by the constant repetition of the same muscular act, although the lesions

¹ "Writers' Cramp and Impaired Writing-power," by C. V. Poore, M. D., *Medico-Chirurgical Trans.*, vol. lxi., 1878.

may vary considerably in the different cases, they may be classed with propriety under the above head; but there is a second class which cannot be so considered, in which there has been a central lesion which has arisen entirely independently of the occupation which has become difficult to perform, and which disability is only one of the many symptoms that have arisen on account of the aforesaid lesion: these are the cases that it is important to differentiate from cases of true copodyscinesia.

When a patient is suffering from a difficulty in performing a fine act of co-ordination where previously there had been no trouble, much information as to the cause may be gained by examining critically the method in which that act is attempted to be carried out; thus, if the patient has a difficulty in writing, his method of holding the pen and his style of writing may throw some light upon the diagnosis; if he holds his pen too firmly or if the down strokes are too heavy, or the writing gradually grows smaller and smaller toward the end of the line, there is a spasm of the flexor muscles; if, on the contrary, the down strokes are imperfectly made or the thumb rises upon the holder, or one finger shows a tendency to straighten itself, the extensors are at fault. Each muscle should then be examined. By asking the patient to make the different movements possible with the fingers and hand of the affected side, and comparing them with those of the sound side, a feebleness of one or more muscles may be detected. The offending muscle may also be detected by electrical examination—by its reacting more or less strongly than its fellow on the other side to the faradic current or showing a quantitative change to the galvanic current.

By stripping the patient to the waist, or at least the arms, and making a careful examination, atrophy or local lesions may be detected that will aid in clearing up the diagnosis.

In telegraphers the mode of manipulating the key should be noted if possible, and the faults made in the different Morse characters studied; this will show as much in this form of the trouble as the mode of writing does in scribes' palsy.

The condition described by Mitchell¹ as post-paralytic chorea may easily be mistaken for these affections, especially where the cerebral lesion was coincident with much manual work (as writing or telegraphing), and was so slight in extent that the paralysis was transient and overlooked, the choreoid movements appearing later, and affecting, as they may do, only the hand. Of this condition Mitchell states "that it may exist in all degrees, with partial loss of power and with full normal strength—that it may consist in mere awkwardness, or exist to the degree of causing involuntary choreoid movements of the parts."

The diagnosis can, in most cases, be satisfactorily arrived at by careful consideration of the history of the case, the mode of onset, the presence of some other signs of cerebral lesion, and the examination of the heart and of the urine.

Some cases of paresis of the arm or hand from lesions of slight extent affecting the arm-centres in the brain (minute emboli, disease of the finer vessels, etc.) might possibly be mistaken for the paretic form of copodyscinesia. Two cases² will illustrate this point:

¹ "Post-paralytic Chorea," by S. Weir Mitchell, *Am. Journ. Med. Sci.*, Oct., 1874.

² From S. Weir Mitchell's notebooks.

Case I.—Mr. G.—, æt. 58, dentist. A great writer, although writing was always a difficult task and soon fatigued him. One day, after excessive writing the day previous, he awoke with a loss of power to write from an inability to properly co-ordinate his muscles; his hand was not unsteady, motion was apparently unimpaired, and his power good, but after laboring for ten or fifteen minutes he would drop the pen. He was treated for writers' paralysis, and gradually improved. One year later he was seized with aphasia and entire loss of power in the right arm and leg. His further history is that of right hemiplegia, and not interesting in this connection.

Case II.—Mr. W.—, civil engineer, æt. 54. Until July, 1881, he considered himself a healthy man, although very excitable; he was then engaged in calculating and writing almost steadily for one week, which exhausted him exceedingly; following this, he was engaged in an abstruse calculation lasting another week, and at the end of this period he awoke to find himself powerless to extend or flex his wrist, and, to use his expression, his thumb would gravitate into his palm. The movements of the shoulder and arm were comparatively unimpaired, and with the exception of occasional dimness of vision of the right eye there was no other symptom noticed. In one week he considered himself well again. In July, one year later, after again passing through a period of exceedingly hard work, he awoke to find that he had lost sensation on the right side and had some difficulty in articulating (muscular). Although thus warned, he worked steadily for twelve hours the next day, in consequence of which he completely broke down. After this he would occasionally write down a wrong word or put down a wrong figure in calculating, etc. One month later he had a transient attack of loss of power in right leg and other signs of partial right hemiplegia, which was in all probability due to an embolus, as there was a marked aortic systolic murmur.

The point brought forward by Axenfield¹ that the paralysis in brain lesions manifests itself equally in all movements of the fingers, while in writers' cramp, etc. there is integrity of all movements except those necessary for the special act, cannot be accepted as diagnostic.

Progressive muscular atrophy, as previously mentioned, bears a close resemblance to professional muscular atrophy (Onimus), which may be considered one of the forms of copodyscinesia. The resemblance, together with the few points of difference, may be best seen in the form of a table, thus:

| PROGRESSIVE MUSCULAR ATROPHY. | PROFESSIONAL MUSCULAR ATROPHY. |
|--|--|
| 1. Heredity in 24.63 per cent. (Roberts). | 1. Heredity not marked. |
| 2. Affects adult males principally. | 2. Affects adult males principally. |
| 3. Frequently follows exhausting muscular activity. | 3. Always follows exhausting muscular activity. |
| 4. Atrophy a cardinal symptom. | 4. Atrophy a cardinal symptom. |
| 5. When it affects the upper extremities, the interossei and the thenar and hypothenar eminences are first affected. (Eulenburg says in his experience the first dorsal interosseus is always first attacked, and the others later.) | 5. The muscles first affected are generally the largest ones, particularly those in the neighborhood of the shoulder-joint. The muscles of the hand may be affected first. |
| 6. Fibrillary twitchings frequent. | 6. Fibrillary twitchings frequent. |

¹ *Des Névroses*, par le Docteur Axenfield, Paris, 1864, p. 339.

7. Premonitory pains rare.

8. Diminution of electrical reactions to both faradism and galvanism. Reaction of degeneration occasionally a late symptom.

9. Prognosis generally unfavorable; as regards perfect restoration of muscles, almost hopeless.

7. Pains and cramps at the onset in the affected parts a distinctive sign.

8. (?)

9. Rapid amendment under rest and the use of constant and continuous electric currents.

The ordinary course of symptoms in this disease is not always followed out, and occasionally the resemblance of the initiatory symptoms to one of the forms of copodyscinesia is great; the following is a case in point:

W. F. G——, æt. 34, clerk, at one time an excessive smoker and a steady writer. In the autumn of 1883 he noticed a numbness on the ulnar side of the tip of the right index finger and on the radial side of the middle third of the right middle finger, at about the points touched by the pen-holder, which he held between these two fingers; this was soon accompanied by a hyperæsthesia to light touches, and the two together seriously interfered with pen-prehension; he then changed the pen to the left hand, and soon noticed a numbness on corresponding points on the left fingers. Any sudden extension of the right arm would cause a thrill to shoot down into the fingers. Weakness of the right opponens pollicis was present at the same time. These symptoms caused the first physician consulted to make a diagnosis of writers' palsy, but the later manifestations of the disease, six weeks subsequently, soon showed its true character: these were marked atrophy of the external portion of the thenar eminence (opponens pollicis) and weakness and partial atrophy, and finally total loss of power, of the anterior group of muscles of right leg (tibialis anticus, extensor proprius pollicis, and extensor longus digitorum); numbness and hyperæsthesia, as in the hand, appeared over instep. Fibrillary twitchings were absent. The affected muscles did not respond to the faradic current, while to the galvanic current there was a quantitative lessening, the reaction still being normal in kind—viz. $KaSZ > AuSZ$.

Paralysis agitans and multiple sclerosis both interfere with writing on account of the tremor of the muscles; the latter disease markedly so, as voluntary effort increases the trembling.

According to Sigerson,¹ the flexors are the least affected in the former disease, and the extensors most so, especially the interossei, which are the earliest involved; the down strokes of the writing will therefore be made with comparative firmness, while the up strokes will show the tremor.²

The writing in multiple sclerosis is much more wavy and irregular, although the same tendency to firmness in the down strokes may still be seen.³

Both these diseases, when well pronounced, should occasion no trouble in diagnosis, but there are cases where the symptoms are not typical, and where the sclerotic change is slight in amount and principally limited to the arm-centres in the cord, or at least to the anterior columns, the symptoms being confined to the finer movements of co-ordination of the hand and arm, and necessarily interfering with such occupations as writing

¹ *Lectures on the Diseases of the Nervous System*, by J. M. Charcot, trans. Philada., 1879, foot-note by Sigerson, p. 113.

² *Ibid.*, p. 112.

³ *Ibid.*, foot-note by Bourneville, pp. 153, 154.

much more than with those which only necessitate coarser movements. The following cases illustrate this point:

Case I.—J. S——, æt. 67, male. Two relatives had paralysis agitans (?). Previous health good; present trouble began nine years ago. Tremor first noticed in writing, and only then, but later any voluntary effort of right arm was accompanied by a fine tremor, which became particularly noticeable when the arm was semiflexed. This is now equal in both arms. When patient writes slowly and with great attention to each movement, he can write fairly for a short time; but if he attempts to write quickly, there is a marked tremor which renders the letters sometimes almost illegible. The up strokes show the most tremor. There is no festination, no change in voice, no loss of power over the sphincters, and no loss of reflexes; the reaction to the galvanic current is normal.

Case II.—W. H——, æt. 58, male. For fifty years the patient has been a hard writer, first as an editor and later as a cashier. In 1882 he noticed difficulty in raising arm to put away papers in pigeon-holes above his head; this movement caused pain in shoulder and arm. Shortly after this he found that his hand became tremulous when he attempted to write, and later any voluntary effort was sufficient to cause the tremor. There has been no cramp. The grip of both hands is good, nor is there any wasting of the muscles. Standing with eyes closed causes no swaying, although there are occasional vertiginous attacks. While walking he has noticed that the right arm does not swing with its usual freedom. No ataxic pains are present. Reflexes of right arm and shoulder are very much exaggerated; there are no changes in nutrition or sensation. Galvanic reaction normal and alike in both arms. The urine is non-albuminous.

The following case is in all probability one of diffused sclerotic changes in the right lateral half of the cord, where the disease has apparently ceased advancing:

Case III.—T. L——, æt. 45. In 1880, three years ago, patient noticed occasional formication in various parts of the right face, hand, and leg, which ceased after he suspended the use of tea and coffee; soon after this he noticed that his writing began to lack ease and that the letters became crowded toward the end of the line; later, a fine tremor appeared in the fingers of the right hand; crampy sensations then appeared in the hamstring muscles of right leg, chiefly while sitting with the knee bent at right angles; writing with the right hand was sufficient to cause, or at least aggravate, this. In 1882 the right arm lost its automatic swing during walking, although holding the left arm still would enable the right arm to swing automatically. Lately the symptoms have ceased advancing, and some seem to improve. His present condition is an inability to write with right hand without paying great attention and making each letter separately, and a trembling of fingers during excitement of any kind. Coarse movements of co-ordination can, as a rule, be well performed; there is no increase of reflexes, nor are they absent; there is no ataxic gait, and there are no trophic changes. Galvanic reaction is normal, and alike on both sides. There is no history of hereditary disease or of venereal taint.

In this connection it is proper to mention tremor mercurialis and

tremor saturninus, which might possibly lead to mistake should proper attention not be paid to the history and to the symptoms. Paul¹ reports a case of the former affection, and gives a specimen of the handwriting of the patient.

Traumatisms, etc. of the various nerves of the arm usually interfere with the proper play of the muscles supplied by them, and although certain of the milder forms of inflammation or of congestion, as previously mentioned, are sometimes present in cases of copodyscinesia, it is manifestly improper to include all cases of impairment of hand-and-arm movement from nerve-injury under this head.

Palsy from pressure, as from sleeping with the head resting upon the arm or with the arm hanging over the back of a chair, is a frequent cause of paresis or paralysis of the muscles supplied by the musculo-spiral.

Tumors pressing upon the nerves in any part of their course, or neuromata, may be mentioned among the more ordinary affections that possibly might mislead.

Tenosynovitis which is described by Hopkins² as a congestion of the tendinous sheaths in the forearm, with insufficient lubrication of the same, causing pain and interfering with motion, might be mistaken for the disease in question, especially as it occurs in many of the same occupations which furnish cases of copodyscinesia.

The exciting cause of tenosynovitis is "usually the resumption of work to which the individual is thoroughly accustomed after a shorter or longer interval when he is out of practice," and not the monotonous repetition of the same act. The differential diagnosis should occasion no difficulty, as there is soreness amounting to positive pain upon motion or pressure along the course of the affected tendons, and the peculiar creaking which is communicated to the finger on palpation.

PATHOLOGY AND MORBID ANATOMY.—Unfortunately for correct determination of the pathological conditions underlying these neuroses, there have been no reported examinations of the spinal cord and nerves in subjects affected with copodyscinesia dying from intercurrent diseases, although it is probable that no macroscopic lesion would be discovered.

Solly³ reports the post-mortem appearance in a case of impaired writing-power in which he found a granular disintegration of the cervical portion of the cord; but this case, from his description, was evidently one in which the impairment of power was merely one of the numerous symptoms dependent upon disease of the cervical cord from degenerative changes, and not a true case of writers' cramp. If such a condition underlaid these neuroses, the cures occasionally reported and the relief frequently felt after the use of the galvanic current could not be explained.

In default, then, of positive information upon this point, conclusions must be drawn from a study of the symptoms, the course, and the behavior of these diseases under treatment. An affection of such protean aspect is not likely to have one settled pathological condition underlying it.

Many affections considered hitherto purely functional have under our

³ *London Lancet*, vol. i. p. 113.

more advanced knowledge been found to have as a basis a positive organic change.

On the subject of fatigue, Poore¹ concisely states that the symptoms "are referable to the muscles, but we must always bear in mind that muscles and motor-nerve are one and indivisible, and that recent experiments have given great probability to the idea that every muscle is connected with a definite spot in the brain; when, therefore, we speak of a sense of fatigue, we must necessarily be in doubt, notwithstanding the fact that the symptoms are referred to the muscles, whether brain, nerve, or muscle, one or all of them, be really at fault."

There is a certain limit to which exercise of a given group of muscles may be carried without producing fatigue and local congestion, or perhaps even inflammatory results; this varies greatly in different individuals, but if it is continually and uninterruptedly overstepped, and insufficient time given for rest and recuperation, the centres in the spinal cord which regulate the action of the various muscles implicated become overstimulated, and the result is an undue amount of nervous energy induced by the peripheral excitation, or there is a distortion of the central impulses in passing through these centres: a perturbation of the co-ordinating power ensues and inco-ordination is the result. Under rest and appropriate treatment these symptoms may pass away, but if the part is continuously used it is highly probable that nutritive changes will be produced in that part of the spinal cord from which the nerves supplying the overtaxed muscles proceed.

In some cases of hemiplegia there is produced during gaping and sneezing an automatic movement of the paralyzed arm; this was noticed as early as 1834 by Marshall Hall,² and in 1872, Onimus³ noticed that movements of the hand and fingers of the non-paralyzed arm produced similar movements in the paralyzed side.

Erb⁴ states that these movements in certain spinal troubles are partly owing to the establishment of conditions of irritation in the neighborhood of the lesion.

Hitzig⁵ states that in certain pathological conditions where the ganglionic elements (in the cord) are superexcitable, the least disturbance produced on one side, and which determines there a voluntary movement, may be communicated to the other side, and provoke, according to the case, either movements similar to a voluntary one or a spasmodic movement which is really a contraction; and also in certain cases relations of the same nature may be established among cellular groups quite distant from each other; and we can comprehend that in these cases the voluntary movements executed by the sound side may be re-echoed in that which is diseased.

This apparent digression bears an important relation to the pathology of copodyscinesia, and lends force to the view that the associated movements which occur in the well arm, or in the affected arm when the sound side is used, or even in the face and legs, and which are quite often seen in these affections, are due to the fact that there is a central change.

Mitchell,⁶ in speaking of functional spasms, states that it will be found

¹ "On Fatigue," *London Lancet*, vol. i., 1875, p. 163.

² Quoted by Charcot, *Diseases of Spinal Cord*, transl. by Comyges, Cincinnati, 1881, p. 110.

³ *Ibid.*

⁴ Quoted by Charcot, *loc. cit.*, p. 124.

⁵ "Functional Spasms," *Amer. J. Med. Sciences*, Oct., 1876.

⁶ *Ziemssen's Cyclopadia*, Amer. ed., vol. xi. p. 409.

in all these cases that when an ordinary functional motor act gives rise to spasms elsewhere, these occur in muscles which have physiological, and therefore anatomical, relations to the muscles which by their normal use give rise to the morbid activities. He considers that there is a hypersensitizing of the sensory centre which takes record of the activities of the affected muscles.

The fact that the left hand becomes implicated in some cases where it is used to relieve the right should be mentioned in this connection as lending weight to this hypothesis, especially as in a few cases of telegraphers' cramp the left hand has been found implicated in the very first attempt to use it in telegraphing.

Poore¹ considers this transfer as no evidence that the change is central, and is one of the few who consider the pathological conditions as purely peripheral in character. Hamilton² and De Watteville³ also consider the peripheral hypothesis the correct one.

Fritz⁴ (and after him Poincaré⁵) considers the disease a reflected neurosis, due to a perversion of the muscular sense. Onimus and Legros⁶ incline to the same opinion.

The older theory that the disease is solely central in its pathology is advocated by Duchenne,⁷ Solly,⁸ Reynolds,⁹ Althaus,¹⁰ Wood,¹¹ Vance,¹² Erb,¹³ Dally,¹⁴ Axenfield,¹⁵ Whittaker,¹⁶ Waller,¹⁷ Gowers,¹⁸ Hammond,¹⁹ Romberg,²⁰ Cederschjöld,²¹ Robins,²² Ross,²³ and some others. Roth²⁴ considers that there are two entirely separate classes, the central and the peripheral or local.

The later theory, that the disease is at first peripheral, but that by abuse may become central (spinal), is advocated by Beard,²⁵ Liebman,²⁶ Bartholow,²⁷ Frazer,²⁸ and a few others. The latter theory, and not the idea that it is a disease of the co-ordinating centres in the brain or of the spinal centres only, best explains, in my opinion, the various symptoms encountered.

Many others have written upon this subject, but upon the probable pathology they have been silent.

The experiments recently made by Dercum and Parker¹ on the artificial induction of convulsive seizures are of considerable interest, and certainly tend to throw light on the point in question. These convulsions were produced by subjecting a group of muscles to a constant and precise effort, the attention being at the time concentrated upon some train of thought. The position most frequently adopted was to cause the arms to be held so that the tips of the fingers barely touched the surface of the table before which the subject was seated, the fingers not being allowed to rest upon the table, but maintained by a constant muscular effort barely in contact with it. After this position was maintained for a variable length of time tremors commenced in the hands; a little later these tremors became rapidly magnified into rapid movements of great extent, sometimes to and fro, sometimes irregular; if the experiment was carried still farther, the muscles of the arms, shoulders, back, buttocks, and legs become successively affected, and the subject was frequently thrown violently to the ground in a strong general convulsion, the consciousness being always retained.² The more frequently these experiments were performed, the more readily the seizures were brought on, and, other things being equal, with successively increasing intensity. One subject thus experimented upon became so susceptible that the jar of a passing wagon sufficed to induce a partial seizure. These experiments throw a new light upon the associated movements previously mentioned, and show how easily the phenomena noticed in one part may pass to another having physiological relationship with it. It is highly probable that some nutritional change in the cord would follow the too frequent repetition of these experiments.

Peripheral pathological conditions undoubtedly exist in many cases of copodyscinesia; these may be so slight that they can scarcely be demonstrated, or, on the other hand, they may be marked, and even present a well-marked inflammation of one or more of the nerves of the arm, as evidenced by pain on motion, tenderness on pressure, and sensory and nutritive disturbances in the areas which they supply.

There are some cases where the disability is pronounced, and yet the most careful examination fails to reveal peripheral changes of sufficient gravity to account for the severity of the symptoms; these, in my opinion, are best explained by supposing a hyperexcitability of the spinal centres, as previously expressed.

The electrical reaction in many cases tends to prove an irritable condition of the spinal centres. In most of the cases of the spastic group there will be found a quantitative increase in the reaction of both nerve and muscle to the galvanic current. Gowers³ states that he has found such an increase in diseases regarded as functional, as paralysis agitans and chorea, and considers it an interesting proof of the molecular changes which underlie or result from functional maladies. He previously re-

¹ "The Artificial Induction of Convulsive Seizures," Dercum-Parker, *The Polyclinic*, Philada. 1884, vol. ii. pp. 95-97.

² These experiments were subsequently repeated before the Philadelphia Neurological Society in 1885.

³ *Dis. of Spinal Cord*, 2d ed., Philada., 1881, p. 40.

marks¹ that such a condition of exalted irritability is to be ascribed to a corresponding change in the nutrition of the nerve-cells of the spinal cord, secondary to the irritative influence which caused it.

Erb² also considers that quantitative increase in the electrical reaction points to central lesion. Buzzard³ quotes several authors upon tetany—which some cases of copodyscinesia closely resemble—who state that the electrical reactions are increased quantitatively in that affection, and considers, himself, that the change is due to central lesion.

It must be borne in mind, however, that in those cases of congestion of the nerves, or neuritis, previously mentioned a quantitative increase may be found, indicating a hypersensitiveness of the peripheral nerve, and not necessarily of the spinal centres.

Poore⁴ states: "Thus we see that alterations of irritability" (he especially alludes to depressions) "accompany many conditions, both central and peripheral," and "there is no necessity for assuming that central change exists in every case of altered irritability, and we have no warrant for such an assumption in the absence of independent evidence of central change."

Exactly what the alteration in the condition of the spinal cord is which probably occurs in many of these cases it is impossible to state, but the view that it is a nutritive change of the upper dorsal and lower cervical portion of the spinal cord (that is, when the arm is the part affected, as it is in all but the rarer cases) is quite attractive, the condition being secondary to a peripheral irritation in many cases.

Althaus⁵ considers that there is a "constriction of the small arteries, dilatation of the veins, and slight serous effusions compressing the nervous matter in the cervical spinal cord."

Pain in the cervical and dorsal spine during work may be mentioned here as an evidence that some of the symptoms are due to central alterations.

Those few cases that exhibit great difficulty in performing one set of movements that requires a certain combination of muscles, but are able to use those same muscles in combination with others with ease, are difficult of explanation by the peripheral theory of the disease alone; but less difficulty is encountered if a superexcitability of the spinal centres is supposed to exist, for here we can imagine that when all the centres so affected are called into use, and only then, there will be an undue amount of nervous energy transmitted to the periphery, and disordered movement be the result.

The explanation offered by those who believe in the peripheral theory is, that the affected muscle is always imperfect in its action, but that this imperfection is masked in other combinations by the action of the healthy muscles, so that it is no longer noticeable.

PROGNOSIS.—The prognosis in these affections varies with the conditions found and with the previous duration of the disease.

A favorable prognosis may generally be given where the case is an acute one, and where the disability can be proved to be due to some one of the peripheral conditions previously mentioned. When the condition is in the forming stage, when fatigue, stiffness, tremor, tingling, aching,

¹ *Med. Times and Gaz.*, London, vol. ii., 1877, p. 536.

² *Loc. cit.*

³ Thomas Buzzard, *Dis. of the Nervous System*, London, 1882.

⁴ "Impaired Writing-power," *loc. cit.*

⁵ *Loc. cit.*

sense of heat, coldness, or powerlessness are the only symptoms which exist, the disease is quite amenable to treatment and a good prognosis may be given; but, unfortunately, patients are loath to believe that these trivial symptoms, which do not prevent their work, are precursors of any serious trouble, and therefore pay but little attention, if any, to them, so that the physician is seldom consulted during this period.

When positive cramp has made its appearance, it is an evidence of a more advanced stage of the malady, and the prognosis becomes less hopeful, although still the symptoms may be greatly ameliorated, or a complete cure even be effected.

When the cramp has existed for years and is present in many of the finer acts of co-ordination, the case becomes almost hopeless as far as cure is concerned; and even though the part is rested, so far as the disabling occupation is concerned, for months or even years, it will be found to return upon resumption of the old work. Roth¹ considers those cases due to central changes totally incurable.

When a congestion of the nerves or a well-defined neuritis is discovered to be the cause of the trouble, the probability of a favorable termination is rather more hopeful.

Paralysis is to be looked upon as an unfavorable symptom, pointing as a rule to a late stage of the disease.

It may be stated with positiveness that when the premonitory symptoms are neglected and constant work persevered in, the case will go on from bad to worse: periods of amelioration, it is true, may occur, but cramp usually supervenes, and the affection becomes gradually progressive as group after group of muscles becomes implicated, until the part becomes useless for all delicate work.

. The probability of the left hand escaping, should it be used to relieve or replace the right, is slight; and for two reasons: 1st. The same predisposition which favored the trouble in the right arm still exists; and, 2d. The proximity of the spinal centres for the two arms is such that the morbid process may easily be conveyed from one to the other, as was shown while considering associated movements.

Poore disbelieves in the possibility of such a transfer, and with Gowers is of the opinion that the liability of the left hand to suffer has been overestimated.

In my experience, as regards telegraph operators, the majority who use the left arm soon notice symptoms of the disability in it. Of 43 cases of this form of copodyscinesia which have come under my observation, in 21 the left arm was implicated; in 12 there was no such implication, although the arm was used; of the remaining 10, 8 had never tried to telegraph or write with the left arm; 1 had only one arm, the left; and 1 was doubtful. Throwing out of consideration the last 10, 21 out of the 33 had this symptom, equivalent to 63.63 per cent.

PROPHYLAXIS.—The only prophylactic measures are the observance of the most easy and least fatiguing method of performing the act which it is feared will bring on the trouble, and the avoidance of overwork.

Tobacco and alcohol generally act injuriously, and therefore should be avoided as much as possible by those who are predisposed by occupation or otherwise to these disorders.

¹ *Loc. cit.*

In writing it is advisable to avoid an awkward manner of holding the pen-holder, which should be of good size; large, moderately soft pens and paper of good quality should be used.

It is also important that the table or desk upon which the writing is done should be of a convenient height, with plenty of room for the arrangement of the paper; otherwise an awkward manner is inevitable.

As regards the position of the paper, R. Berlin¹ (Stuttgart) states substantially as follows: In writing the head is almost invariably held so that the line passing through the two eyes, if projected upon the paper, shall cross at right angles the oblique line of the writing: when the paper is placed to the right and parallel to the edge of the table, as generally directed by teachers, the tendency is to twist the spine and incline the head to the right in order to conform to this rule, and a cramped position is the result; but by placing the paper in an oblique position directly in front of the writer—*i. e.* turned toward the left—this cramped position is avoided, and the least fatigue, both to the muscles of the spine and arm, produced. Tight sleeves or anything that might possibly impede the free play of the muscles or cause pressure upon the nerves should be discarded.

It is now almost universally conceded that the conjoint movement in writing—that is, the arm movement for all the small letters, and the finger movement only to assist in making the long ones—is least likely to produce fatigue.

It has been stated, and quite generally believed, that the slighter degrees of scriveners' palsy are relieved by avoiding contact with the metallic portion of the pen-holder,² and one of the methods taken to avoid this contact, especially among telegraph operators, is to slip a piece of rubber tubing over the pen-holder; this certainly does relieve the fatigue slightly, but the cause is not the avoidance of contact with metal or the insulation, etc., but simply that the holder is thus made larger and softer for the fingers, and thus takes the place of a cork pen-holder, which for some time has been in use for this purpose.

Holding the pen-holder or pencil between the different fingers is another prophylactic measure, and relieves fatigue considerably; for instance, when it is placed between the index and middle fingers there is much less effort at pen-prehension, and the fingers may be temporarily rested without any effort to hold the pen-holder, as the friction between the fingers keeps it in position. This method is frequently adopted by stenographers.

The typographic and Mackinnon pens, although they destroy much of the originality in handwriting, are easier to write with than a pen, as less pressure is needed and no particular angle is required to be maintained between the point and the paper.

The type-writer is one of the newer inventions destined to come into extended use for the purpose of relieving the fatigue of writing, which it does to a marked degree, besides having other merits; and although one of these is said to be the immunity of its users from writers' cramp,

¹ "Physiology of Handwriting," *Von Graef's Archiv*, xxviii. p. 259, review in *Ophth. Review*, London, vol. i. No. 14, Dec., 1882, and Jan. 1, 1883.

² W. Bathurst Woodman, St. Andrews Grad. Ass., 1872-73.

I venture to assert that cases of this class of trouble will ensue from its over-use, exactly as they do in piano-playing.¹

Thurber's kaligraph, which was invented before the type-writer, has never come into general use: it works upon the principle of a penta-graph, and all finger movements are done away with and the arm movement used exclusively, the motions of writing being much coarser than ordinary. This instrument is not as well adapted for prophylaxis in these troubles as it is for use in some deformities of the hand hindering pen-prehension, as rheumatoid arthritis, contractions after burns, etc.

In regard to the means to be taken to avoid the occurrence of telegraphers' cramp, but little can be said, except that if any of the premonitory symptoms of the neurosis should occur (fatigue, pain, tingling, numbness, flushing, associated movements, etc.) after performing the amount of work which previously caused no discomfort, it should be taken as a warning that the operator is attempting more work than can be done without detriment, and that a curtailment of the work is absolutely necessary if he or she wishes to avoid the disease.

Onimus² has said that if further investigation proves that the operators upon the Morse instrument are more liable to suffer than those using other systems, it should be the duty of those in authority to abolish that system and adopt some other: he suggests for this object the Hughes, which is a printing instrument. That the operators upon the Morse are more liable to suffer than any others is self-evident after a very slight inquiry, and because of the very general introduction of that machine. This instrument is far more practical, takes up less room, and is less likely to get out of order, than any other yet invented, and no other, it is probable, will be introduced so generally. The telephone has not diminished the amount of work for the telegraph operator, but has given rise to a new industry. In all of the systems the instruments are manipulated at least in part by the fingers, so that all are liable to cause this disease.

The telegraph key should be placed some distance from the edge of the table, so that the forearm may have sufficient support, resting upon the bellies of the flexor group of muscles, and thus relieve the shoulder-muscles, which otherwise would have to support the weight of the arm. Some operators prefer to hold the arm raised from the table, but this method is more liable to cause fatigue.

Several keys have been invented for the purpose of lessening the amount of force needed to manipulate them, and to avoid the jarring caused by the metallic contact; and, although everything that lessens the amount of labor should be adopted, the movements of telegraphing must remain the same no matter which key is used.

Tapping upon the key or attempting to operate by flexing the fingers while the wrist is held still should be avoided.

It is needless to enumerate the other forms of copodyscinesia, as the same general principles apply to the prophylaxis of all.

TREATMENT.—Rest.—It is an assured fact that as long as the patient continues without curtailment the amount of work he was performing

¹ To print this article by this machine would require nearly one hundred and fifty thousand separate flexions of the fingers.

² *Loc. cit.*

when the symptoms of this trouble appeared, treatment will be negative in its results. Rest in itself is powerless to cure, except in the very earliest stages of the disease, for many sufferers have found, to their dismay, that after having given the arm complete rest, as far as the disabling occupation was concerned, for months at a time, the symptoms reappear upon returning to the accustomed work.

During treatment rest is essential, but this need not of necessity be complete; a curtailment of the work will often be all that is needed in the lighter cases. This may be effected by using the unaffected arm for a part of the work at least, but great care must be exercised lest the symptoms appear on this side also, as the left arm, from want of use, is wanting in strength and dexterity, and is more liable to be overtaxed by an amount of work that could be performed without fatigue by the right; for should this happen the end sought for is defeated, and the condition of the patient rendered far worse than before.

In writers' cramp the type-writer, as mentioned under Prophylaxis, is an important adjuvant in the treatment; unfortunately, it is not applicable to much of the work done by clerks.

The other means described in the last section are also useful in the treatment as affording temporary rest to the affected muscles. Hamilton¹ has seen occasional benefit from forced rest by fastening the hand upon a splint.

In telegraphing, besides using the left arm, the key may be grasped in a different manner, or if the operator has been holding his arm raised from the table, let him rest it upon the latter, or vice versa.

These remarks only apply to those who are compelled to continue moderate work during treatment.

Electricity.—The majority of the later writers unite in considering electricity as one of the most important agents in the treatment of these affections: the form and the manner in which it is applied are, however, all important.

The faradic or secondary current has often been tried in undoubted cases of copodyscinesia, and in the majority has failed. It may be of great service in the paralytic group, where the affected muscle shows signs of atrophy and of being temporarily deprived of nerve-influence; it may be also of service in those apparent cases of the spastic group due to contracture of the unopposed muscles, but in the vast majority, where there is a true spasm of the affected muscles or a tendency in that direction, as evinced by rigidity more or less pronounced during work, or even where there is only a quantitative increase to either current (faradic or galvanic), the application of this form of electricity is contraindicated, as the muscular contraction is already excessive, and should this extra stimulus be applied the muscle may be exhausted, for we know how readily this effect may be produced by a too strong or a too lengthy application in a perfectly healthy subject.

It is hardly necessary to mention that the manner of applying electricity so often followed by individuals—viz. holding the electrodes in the palms of the hands—is unscientific and productive of no good. The proper method of application in the suitable cases is to place one electrode of the secondary coil (preferably the negative, so called) over

¹ *Loc. cit.*

the muscle that is weakened or over its nerve-point, and the other in some indifferent position, using a current that is just strong enough to cause a fair contraction, and employing a slow interrupter, which breaks the current from one to four times a second. The application should be short, five to ten good contractions of each muscle being sufficient.

Buzzard¹ has used this current with success in two cases of impaired writing-power, one of these depending upon a local paralysis. Zuradelli,² Meyer,³ and Haupt⁴ have also seen good results by this method. Duchenne⁵ states that he has "not even seen one success obtained by those who have praised this method of treatment." The majority of the later writers coincide with this last opinion as regards the spastic form at least.

The galvanic current has of late been considered one of the most important agents in the treatment of these affections, but there is considerable variance among authorities as to how it should be applied. The most efficacious method is the descending current (anode on the spine and the cathode at the periphery), as this has been found to be more soothing in its effects than the reverse. The anode should be placed upon the spine over the cervical cord, and the cathode in the hand of the affected side or over the affected muscles or nerves.

A stabile current—*i. e.* where the poles are not moved about—is to be preferred to a labile current—*i. e.* where the poles are moved constantly—as this is more stimulating than the former; but if a current of proper strength is used, one that can be plainly felt when the circuit is made and broken only, the importance of the stabile over the labile does not obtain.

The treatment should not be prolonged for more than fifteen or twenty minutes, and may be repeated three times a week or every other day.

Onimus and Legros⁶ recommend this mode of treatment, but from a different pathological standpoint, as they consider the neurosis to be an excitability of the sensitive nerves of the muscles, and employ the descending current to allay this.

All sudden shocks or reversals of the current should be avoided in the treatment, although this may be necessary in using the galvanic current for diagnosis.

As the seat of the trouble in many cases is probably in the cervical cord, it is well that special treatment should be applied to this part, and for this purpose Althaus⁷ recommends that the anode be placed, as previously mentioned, over the cervical cord, and the cathode in the depression between the angle of the lower jaw and the sterno-cleido-mastoid muscle, which position corresponds to the superior cervical ganglion of the sympathetic. The current should be allowed to flow from three to five minutes at a time; it should be a mild one, and not be broken or increased or diminished suddenly, as vertigo may be produced. Both sides should be treated should the left hand be suffering also. A reversal of this method—*i. e.* cathode to spine—does little if any good, according to the same author.

⁷ *Loc. cit.*

Poore¹ employs the descending stabile current of a strength just short of producing muscular contraction when the current is broken, but at the same time he employs rhythmical movements of the muscles supplied by the nerve upon which the cathode is placed during the flow of the current.

A novel mode of applying the galvanic current in scriveners' palsy has been recommended by Imlach.² He has an electric desk so constructed that when the patient makes the movements of writing the extensors and flexors are alternately galvanized, the muscles being thus assisted in their movements. While this might be of service in some cases, it is entirely too complicated for practical use. He reports one case benefited by its use.

Franklinic or Static Electricity.—This form of electricity is now being much used, especially abroad, in the treatment of nervous affections, but does not appear to have been employed in the different copodyscinesia, as but few reports of such treatment have found their way into current literature. Romain Vigouroux³ states that he has cured one case by static electricity. Another case is reported by Arthuis⁴ as rapidly cured by this treatment after many other means, carried on during a period of five years, had failed; but his brochure contains too many reports of cures of hitherto incurable diseases to be relied upon.

Gymnastics and Massage.—As those suffering from copodyscinesia are generally compelled by their vocation to be more or less sedentary, exercise in the open air is indicated, inasmuch as it tends to counteract the evil effects of their mode of life; but the use of dumb-bells or Indian clubs, riding, rowing, and similar exercises do not ward off the neuroses in question or diminish them when they are present.

Such is not the case when rhythmical exercises and systematic massage of all the affected muscles are employed, as marked benefit has followed this method of treatment. The method employed by J. Wolff, a teacher of penmanship at Frankfort-on-the-Main, which consists of a peculiar combination of exercise and massage, appears to have been wonderfully successful, judging from his own statements and editorial testimonials of such eminent men as Bamberger, Bardenleben, Benedikt, Billroth, Charcot, Erb, Esmarch, Hertz, Stein, Stellwag, Vigouroux, Von Nussbaum, Wagner, and De Watteville. The method is described by Romain Vigouroux⁵ and Th. Schott,⁶ the latter claiming priority for himself and his brother, who employed this method as early as 1878 or 1879. Wolff,⁷ however, states that he had successfully treated this disease by his method as early as 1875. Theodor Stein,⁸ having had personal experience in Wolff's treatment, also describes and extols it: 277 cases of muscular spasms of the

upper extremities were treated; of these, 157 were cured, 22 improved, while 98 remained unimproved; these comprised cases of writers', pianists', telegraphers', and knitters' cramp.

It must be borne in mind that Wolff, not being a physician, can refuse to treat a case if he thinks it incurable; and in fact he does so, as he has personally stated to the writer, so that his statistics probably show a larger percentage of cures than otherwise would be the case.

His method may be described as follows: It consists of a combined employment of gymnastics and massage; the gymnastics are of two kinds: 1st, active, in which the patient moves the fingers, hands, fore-arms, and arms in all the directions possible, each muscle being made to contract from six to twelve times with considerable force, and with a pause after each movement, the whole exercise not exceeding thirty minutes and repeated two or three times daily; 2d, passive, in which the same movements are made as in the former, except that each one is arrested by another person in a steady and regular manner; this may be repeated as often as the active exercise. Massage is practised daily for about twenty minutes, beginning at the periphery; percussion of the muscles is considered an essential part of the massage. Combined with this are peculiar lessons in pen-prehension and writing.

The rationale of this treatment is not easy, but any method which even relieves these neuroses should be hailed with pleasure, as they heretofore have been considered almost incurable.

The method employed by Poore, as mentioned under Electricity, of rhythmical exercise of the muscles during the application of the galvanic current, is worthy of further trial, as it combines the two forms of treatment hitherto found most successful.

Internal and External Medication.—Generally speaking, drugs are of comparatively little value in the treatment of these affections. This statement does not apply to those cases where the symptoms are produced by some constitutional disorder, or where there is some other well-recognized affection present which does not stand in relation to these neuroses as cause and effect.

In any case where an accompanying disorder can be discovered which is sufficient in itself to depress the health, the treatment applicable to that affection should be instituted, in the hope, however unlikely it is to be fulfilled, that with returning health there will be a decrease of the copodysinesia. In the majority of cases no constitutional disease can be detected, and it is in these that internal medication has particularly failed.

The following are some of the remedies that have been employed: Cod-liver oil, iron, quinine, strychnia, arsenic, ergot, iodoform, iodide and bromide of potassium, nitrate of silver, phosphorus, physostigma, gelsemium, conium, and some others.

Hypodermic Medication.—Atropia hypodermically, as first suggested by Mitchell, Morehouse, and Keen¹ in the treatment of spasmodic affections following nerve-injury, has been used with good effect in those cases where there is a tendency to tonic contraction; it should be thrown into the body of the muscle. Vance² speaks very favorably of one-sixtieth

¹ *Gunshot Wounds and Other Injuries to Nerves*, Philada., 1864.

² Reuben A. Vance, M. D., "Writers' Cramp or Scriveners' Palsy," *Brit. Med. and Surg. Journal*, vol. lxxxvii. pp. 261-285.

of a grain of atropia used in this manner three times a week. Morphia, duboisia, and arsenic in the form of Fowler's solution have been used hypodermically with but little effect. Rossander¹ reports a cure in one month of a case of two years' duration by the hypodermic use of strychnia. Onimus and Legros² used curare in one case without effect.

Local Applications.—The apparent benefit following the local application of lotions, etc. to the arms in some cases appears to be as much due to the generous kneading and frictions that accompany them as to the lotions themselves. Onimus and Legros, believing the lesion to be an excitability of the sensitive nerves at the periphery, employed opiated embrocations, but report amelioration in one case only.

When there are symptoms of congestion of the nerves or of neuritis, then the proper treatment will be the application of flying blisters, or the actual cautery very superficially applied to the points of tenderness from time to time, so as to keep up a continual counter-irritation. This treatment may be alternated with the application of the galvanic current (descending, stabile, as previously mentioned) or combined with it. As these conditions are often found in nervous women, care should be taken lest this treatment be too vigorously carried out.

Considerable relief has been reported from the use of alternate hot and cold douches to the affected part—a procedure which is well known to do good in some cases of undoubted spinal disease; the application peripherally applied altering in some way, by the impression conveyed to the centres, the nutrition of the spinal cord.

Tenotomy.—Tenotomy has been but little practised for the cure of these affections. Stromeyer³ cut the short flexors of the thumb in a case of writers' cramp without any benefit, but in a second case, where he cut the long flexor of the thumb, the result was a cure. Langenbeck⁴ quotes Dieffenbach as having performed the operation twice without success, and states that there has been but one observation of complete success, and that was the one of Stromeyer. Aug. Tuppert⁵ has also performed this operation, and Haupt⁶ advises it as a last resource.

Very few would be willing to repeat the experiment in a true case of copodyscinesia after the failures above enumerated, for the temporary rest given the muscle does not prove of any more service than rest without tenotomy, which has failed in all the more advanced cases, which are the only ones where tenotomy would be thought of.

Nerve-Stretching.—It is curious that no cases have been reported (at least I have not been able to discover them) of nerve-stretching for aggravated cases of copodyscinesia, as the operation has been performed in several cases of local spasm of the upper extremity following injuries to the nerves.

Von Nussbaum⁷ alone mentions the operation, and states that it has been of no avail, but gives no references; he previously⁸ stretched the ulnar nerve at the elbow and the whole of the brachial plexus for spasm

of the left pectoral region and of the whole arm, following a blow upon the nape of the neck; the patient made a good recovery.

This operation, according to an editorial in the *American Journal of Neurology*,¹ has been performed seven times for spastic affections of the arm with the following results: 2 cures (1 doubtful), 3 great improvement, and 2 slight relief.

This procedure would seem to be indicated in those cases of copodyscinesia where spasms are present which have a tendency to become tonic in their character, where other means of treatment have failed. One such case has fallen under the writer's notice, which, on account of its singularity and the rarity of the operation, seems worthy of record. The patient is a physician in large practice, and his account, fortunately, is more exact than it otherwise would be:

— — —, æt. 36. Paternal uncle had a somewhat similar trouble in right arm, father died of paralysis agitans, and one brother has writers' cramp. From nine to twelve years of age he was considered an expert penman, and was employed almost constantly, during school-hours, writing copies for the scholars. At the age of eleven he began to feel a sense of tire in right forearm and hand when writing; soon after this the flexors of right wrist and hand began to contract involuntarily and become rigid only when writing. He remembers being able to play marbles well for two years after the onset of the first symptoms. The trouble gradually increased until every motion of the forearm became involved. At the age of nineteen he became a bookkeeper, using his left hand, but at the end of one year this became affected also. Since then both arms have been growing gradually worse, and at one time exhaustion would bring on pain at the third dorsal vertebra. At the age of thirty a period of sleeplessness and involuntary contractions of all the muscles of the body came on, accompanied by difficulty in articulation from muscular inco-ordination. After persistent use of the cold douche to spine these symptoms ameliorated, but the general muscular twitching sometimes occurs yet, and overwork brings on spasm of the extensors of the feet. The condition of his arms in December, 1882, was as follows: At rest the right forearm is pronated, the wrist completely flexed and bent toward the ulnar side, the thumb is slightly adducted, and the fingers, although slightly flexed, are comparatively free, enabling him to use the scalpel with dexterity. This contraction can be overcome by forcibly extending the fingers and wrist and supinating forearm, but if the arm be now placed in supination the following curious series of contractions occur, occupying from one to two minutes from their commencement to their completion: gradually the little finger partially flexes, then the ring, middle, and fore finger follow in succession; the wrist then slowly begins to flex and to turn toward the ulnar side, and finally the arm pronates, in which position it will remain unless disturbed. The contraction is accompanied by a tense feeling in the muscles, but is painless. The left arm behaves in a somewhat similar manner, and if this is placed in supination a gradual pronation of the arm begins; then follows the flexion of the fingers, commencing with the little finger and ending with the thumb; the wrist also flexes, but not as much as the right, although the flexion of the fingers is more marked. There is no pain on pressure over

¹ *Am. Journ. of Neurology and Psychiatry*, 1882.

muscles or nerves. The extensor muscles of both arms, although weaker than normal, are not paralyzed, those of the right responding more readily to both faradic and galvanic currents than do the left. There is no reaction of degeneration. The flexors respond too readily, the right showing the greatest quantitative increase.

In 1879, while abroad, his condition being essentially as above described, he consulted Spence of Edinburgh, who as an experiment stretched the left ulnar nerve at the elbow; immediately after the operation the muscles were paralyzed and the arm remained quiet; in twenty-four hours the nerve became intensely painful, and remained so, day and night, for three weeks; this gradually subsided, and ceased with the healing of the wound two weeks later. Forty-eight hours after the operation the spasm of the muscles returned, and in a short time became as bad as ever, proving the operation to have been a failure.

An interesting point to decide in this case is whether the symptoms point to an abnormal condition of the nerve-centres, first manifesting itself in difficulty of writing, or whether the constant writing induced a superexcitability (for want of a better term) of the spinal cord in a patient markedly predisposed to nervous troubles. This last hypothesis I believe to be the correct one.

It might be considered at first sight that the symptoms presented by this patient were due to a paralytic condition of the extensors, and not a spasm of the flexors, or at least that the latter was secondary to the former. While the extensors are somewhat weaker than normal from want of use, a careful study of the mode of onset of this affection and the symptoms presented later prove this idea to be erroneous.

In regard to the operation and its results, it seems that a fairer test of the efficacy of nerve-stretching in this case would have been made if the median and not the ulnar nerve had been stretched, as the latter only supplies in the forearm the flexor carpi ulnaris and the inner part of the flexor profundus digitorum, while the former supplies the two pronators and the remainder of the flexor muscles.

Of the mode of action of this operation we are still much in the dark, but it would seem to be indicated in any case where the contractions are very marked and tonic in their nature—not, however, until other means have failed to relieve.

In the ordinary forms of copodyscinesia, it is needless to say, the operation would be unjustifiable.

Mechanical Appliances.—Most of the prothetic appliances have been devised for the relief of writers' cramp, the other forms of copodyscinesia having received little if any attention in this direction. The relief obtained by their use is usually but temporary, especially if the patient attempts to perform his usual amount of work, which is generally the case.

These instruments are of undoubted benefit when used judiciously in conjunction with other treatment, as by them temporary rest may be obtained, or in some cases the weakened antagonists of cramped muscles may be exercised and strengthened. They all, without exception, operate by throwing the work upon another set of muscles, and failure is almost sure to follow their use if they alone are trusted in, as the new set of muscles sooner or later becomes implicated in the same way that the left hand is apt to do if the whole amount of work is thrown upon it.

To accurately describe these instruments is out of place in this article: those wishing to study this branch of the subject more fully are referred to the article by Debout,¹ where drawings and descriptions of the most important appliances are given.

Their mode of action may be considered under the following heads:

I. Advantage is taken of muscles as yet unaffected, which are made to act as splints (so to speak) to those affected, greater stability being thus given and cramp controlled when present.

Under this head may be mentioned the simple plan of placing a rubber band around the wrist, wearing a tight-fitting glove, or applying Es-march's rubber bandage with moderate firmness to the forearm. Large cork pen-holders, by distributing the points of resistance over a larger surface, are thus much easier to hold than small, hard pen-holders.

Two of the instruments devised by Cazenave—one, consisting of two rings joined together in the same plane (to which the pen-holder is attached), and through which the index and middle fingers are thrust as far as the distal joints; and another consisting of two rings of hard rubber, one above the other, sufficiently large to receive the thumb, fore and middle fingers, which are thus held rigidly in the writing position—act in this manner, and are used when the cramp affects the thumb or fore finger.

II. The cramp of one set of muscles is made use of to hold the instrument, the patient writing entirely with the arm movement.

The simple plan of grasping the pen-holder in the closed hand, as previously described, or of thrusting a short pen-holder into a small apple or potato, which is grasped in the closed hand, occasionally affords relief and acts in this way. The instruments of Mathieu, Velpeau, Charrière, and one by Cazenave are based upon this principle. The first consists of two rings rigidly joined together about one inch apart, one above the other, through which the fore finger is thrust, and of a semicircle against which the tip of the thumb is pressed; the pen-holder is attached to a bar adjoining the semicircle and rings. Velpeau's apparatus consists of an oval ball of hard rubber carrying at one extremity the pen-holder at an angle of 45° ; the ball is grasped in the closed hand, and the pen-holder allowed to pass between the fore and middle fingers. Charrière's instrument is a modification of the last, having in addition to the ball a number of rings and rests for the fixation of the fingers. The latter has also devised an instrument consisting of a large oval ball of hard rubber; this is grasped in the outstretched palm, which it fills, and is allowed to glide over the paper; the pen-holder is attached to one side. Cazenave's instrument is simply a large pen-holder with rest and rings to fix the fingers.

III. The instrument prevents the spasm of the muscles used in poisoning the hand from interfering with those used in forming the letters.

One of the instruments devised by Cazenave acts in this way: it consists of a small board, moving upon rollers, upon which the hand is placed; lateral pads prevent the oscillations of the arm due to spasmodic action of the supinators. The pen-holder is held in the ordinary manner.

IV. The antagonistic muscles to those affected by cramp are made to hold the instrument, while the cramped muscles are left entirely free.

¹ "Sur les Appareils prothétiques, etc.," *Bull. de Thérap.*, 1860, pp. 327-377.

But one instrument acts in this manner—viz. the bracelet invented by Von Nussbaum,¹ which consists of an oval band of hard rubber to which the pen-holder is attached. The bracelet is held by placing the thumb and the first three fingers within it and strongly extending them.

The inventor claims great success by its use alone, as the weakened muscles are exercised and strengthened and the cramped muscles given absolute rest.

Résumé of Treatment.—In the complicated cases of copodyscinesia rest of the affected parts, as far as the disabling occupation is concerned, must be insisted upon: this should be conjoined with the use of the galvanic descending stable current, combined with rhythmical exercise of the affected muscles and of their antagonists, and massage. Where there is evidence of a peripheral local congestion or inflammation, this must be attended to; for instance, if there is congestion of the nerves, or neuritis, flying blisters or the actual cautery should be applied over the painful spots, followed by the galvanic current. Where there is paralysis of one or more muscles, with evidence of interference of nerve-supply, the faradic current may be used with advantage.

Evidences of constitutional disease should lead to the employment of the treatment suitable for those affections.

RÉSUMÉ OF 43 CASES OF TELEGRAPHERS' CRAMP.

TETANUS.

By P. S. CONNER, M. D.

TETANUS (*τεινω*, to stretch) is a morbid condition characterized by tonic contraction of the voluntary muscles, local or general, with clonic exacerbations, occurring usually in connection with a wound. Cases of it may be classified according to cause (traumatic or idiopathic); to age (of the new-born and of those older); to severity (grave and mild); or to course (acute and chronic), this latter classification being the one of greatest value.

Though known from the earliest times, it is in the civil practice of temperate regions of comparatively rare occurrence, and even in military surgery has in recent periods only exceptionally attacked any considerable proportion of the wounded.

Occurring in individuals of all ages, the great majority of the subjects of it are children and young adults. Women seem to be decidedly less liable to it than men. That this is due to sexual peculiarity may well be doubted, since the traumatic cases are by far the most numerous, and females are much less often wounded than males. The traumatism of childhood are occasionally followed by it (puerperal tetanus).

That race has a predisposing influence would appear to be well established; the darker the color, the greater the proportion of tetanics. Negroes are especially likely to be attacked with either the traumatic or idiopathic form.

Atmospheric and climatic conditions, beyond question, act powerfully in, if not producing at least favoring, the development of tetanus. Places and seasons in which there is great difference between the midday and the midnight temperature, the winds are strong, and the air is moist, are those in which the disease is most prevalent; and it is because of these conditions that the late spring and early autumn are the periods of the year when cases are most often seen.¹

Cold has, from the time of Hippocrates, been regarded as a great predisposing if not exciting cause, and the non-traumatic cases have been classed together as those a frigore. It is not, however, the exposure to simply a low temperature that is followed by the disease, but to cold combined with dampness, and quickly succeeding to a temperature decidedly

¹ In his account of the Austrian campaign of 1809, Larrey wrote: "The wounded who were most exposed to the cold, damp air of the chilly spring nights, after having been subjected to the quite considerable heat of the day, were almost all attacked with tetanus, which prevailed only at the time when the Reaumur thermometer varied almost constantly between the day and the night by the half of its rise and fall; so that we would have it in the day at 19°, 20°, 21°, and 23° above zero (75°-84° F.), while the mercury would fall to 13°, 12°, 10°, 9°, and 8° during the night (50°-61° F.). I had noticed the same thing in Egypt."

higher, as in the cool nights coming on after hot days in tropical regions, or in the spring and fall seasons of temperate latitudes, or in the cold air blowing over or cold water dashed upon a wound or the heated skin. That such cold, thus operating, does most usually precede the attack of tetanus is unquestionable; and it has by many been held that without it no traumatism will be followed by the disease. Observers generally are agreed, with Sir Thomas Watson, that "there is good reason for thinking that in many instances one of these causes (wound and cold) alone would fail to produce it, while both together call it forth."

In the low lands of hot countries (as the East and West Indies) the disease is very frequently met with, at times prevailing almost epidemically; and, on the other hand, it is rare in dry elevated regions and in high northern latitudes, as in Russia, where during a long military and civil experience Pirogoff met with but eight cases. Trismus nascentium would seem to be an exception to the general rule of the non-prevalence of tetanus in places far north, since, *e. g.*, it has been at different periods very common in the Hebrides and the small islands off the southern coast of Iceland. But these localities, from their peculiar position, are not extremely cold, and their climate is damp and variable; so that, even if the lockjaw of infants be accepted as a variety of true tetanus, the geographical exception indicated is but an apparent one.

Traumatic cases are greatly more numerous than idiopathic, and no class of wounds is free from the possibility of the supervention of tetanus. Incised wounds are much less likely to be thus complicated than either of the other varieties, though operation-wounds of all sorts, minor and major, have been followed by this affection. So frequently has it been associated with comparatively trivial injuries that it has become a common belief that the slighter the traumatism the greater the danger of tetanus. That this is not true the records of military surgery abundantly show. Wounds of the lower extremity are much graver in this respect than those of the upper. Injuries of the hand and feet, especially roughly punctured wounds of the palmar and plantar fasciæ (as, *e. g.*, those made by rusty nails), have long been regarded as peculiarly liable to develop the disease, and accidents of this nature always give rise to the fear of lockjaw. Though there can be no question but that more than one-half of the cases of tetanus in civil life are associated with wounds of these localities, yet the number of such injuries is so much greater than of those of other parts of the body that the special liability of the subjects of them to become tetanic may well be questioned. In this connection it is a significant fact that during our late war of perhaps 12,000 or 13,000 wounds of the hand, only 37 were followed by tetanus, and of 16,000 of the foot, but 57. A few years ago numerous cases of tetanus were observed in our larger cities complicating hand-wounds produced by the toy pistol—injuries that were often associated with considerable laceration of the soft parts, and generally with lodgment of the wad.

Not even the complete cicatrization of a wound altogether protects against the occurrence of the disease, the exciting cause of which, under such circumstances, is probably to be found in retained foreign bodies or pent-up fluids.

ETIOLOGY.—Almost universally regarded as an affection of the central nervous system, inducing a heightened state of the reflex irritability,

though some have maintained that the reflex excitability of the medulla and the cord is actually lessened, how such affection is produced is unknown; and it is an unsettled question whether it is through the medium of the nerves or the vessels, whether by ascending inflammation, by reflected irritation, or by the presence of a septic element or a special micro-organism in the blood.

That the disease is due to ascending neuritis finds support in the congested and inflamed state of the nerves leading up from the place of injury (affecting them in whole or in part, it may be in but a few of their fibres), and in the inflammatory changes discoverable in the cord and its vessels. But time and again thorough and careful investigation by experienced observers has altogether failed to detect any alterations in the nerves or pathological changes in the cord, other than those that might properly be attributed to the spasms, the temperature, or the drugs administered. The symptoms of acute neuritis and myelitis (pain, paralyses, and later trophic changes) are not those which are present in cases of tetanus. The evidences of inflammation of the cord are most apparent, not in that portion of it into which the nerves from the wounded part enter, but, as shown by Michaud, so far as the cellular changes in the gray matter are concerned, always in the lumbar region, no matter where the wound may be located.

The much more generally accepted theory of reflex neurosis is based upon the association of the disease with "all forms of nerve-irritation, mechanical, thermal, chemical, and pathological;" upon the direct relation existing between the likelihood of its occurrence and the degree of sensibility of the wounded nerve;¹ in the, at times, very short interval between the receipt of the injury and the commencement of the tetanic symptoms; in the local spasms unquestionably developed by nerve-pressure and injury; in the primary affection of muscles at a distance from the damaged part; in the already-referred-to absence of the structural lesions of inflammation; and in the relief at times afforded by the removal of irritating foreign bodies, the temporary cutting off of the nerve-connection with the central organs, or the amputation of the injured limb. But that something more than irritation of peripheral nerves is necessary to the production of tetanus would seem to be proved by the frequency of such irritation and the rarity of the disease; by the not infrequent prolonged yet harmless lodgment of foreign bodies, even sharp and angular ones, against or in nerves of high sensibility;² by the primary affection of the muscles about the jaws, and not those in the neighborhood of the wound; by the almost universal failure to produce the affection experimentally, either by mechanical injuries or by electrical excitations; by certain well-attested instances of its repeated outbreak in connection with a definite locality, a single ship of a squadron, a particular ward in a hospital, or even bed in a ward; by the usual absence of that pain which is the ordinary effect of nerve-irritation; and by the small measure of success which has attended operations, even when early performed, per-

¹ According to Gubler, the danger is greatest in wounds of parts containing numerous Pacinian corpuscles.

² Heller has reported a case in which a piece of lead was lodged in the sheath of the sciatic nerve. Though chronic neuritis resulted, the wound healed perfectly. Two years later, after exposure while drilling, the man was seized with tetanus and died of it.

mitting the taking away of foreign bodies pressing upon or resting in a nerve, interrupting the connection with the cord, or altogether removing the wound and its surroundings. Even in the idiopathic cases—many of which, it would at first sight appear, can be due only to reflected irritation—another explanation of the mode of their production may, as we will see, be offered.

The so-called humoral theory would find the exciting cause of the disease in a special morbid agent developed in the secretions of the unbroken skin or the damaged tissues of the wound, or introduced from without and carried by the blood-stream to the medulla and the cord, there to produce such cell-changes as give rise to the tetanic movements. It finds support in the unsatisfactory character of the neural theories; in the strong analogy in many respects of the symptoms of the disease to the increased irritability and muscular contractions of hydrophobia and strychnia-poisoning, or those produced by experimental injections of certain vegetable alkaloids; in the recent discoveries in physiological fluids, as urine and saliva, of chemical compounds,¹ and in decomposing organic matter of ptomaines capable of tetanizing animals when injected into them; in the rapidly-enlarging number of diseases known to be, or with good reason believed to be, consequent upon the presence of peculiar microbes; in the more easy explanation by it than upon other theories of the ordinary irregularity and infrequency of its occurrence, its occasional restriction within narrow limits, and its almost endemic prevalence in certain buildings and even beds; in the extreme gravity of acute cases and the protracted convalescence of those who recover from the subacute and chronic forms; in the very frequent failure of all varieties of operative treatment; and in the success of therapeutic measures just in proportion to their power to quiet and sustain the patient during the period of apparent elimination of a poison or development and death of an organism.

This theory is as yet unsupported by any positive facts. Neither septic element nor peculiar microbe has been discovered.² Failure has attended all efforts to produce the disease in animals by injecting into them the blood of tetanics. There is no testimony worthy of acceptance of the direct transmission of the disease to those, either healthy or wounded, coming in contact with the tetanic patient; nor can much weight be attached to such reports as that of Betoli of individuals being attacked with it who had eaten the flesh of an animal dead of it.

The ordinary absence of fever has been thought to prove the incorrectness of this theory, but increased body-heat is not a symptom of rabies or strychnia-poisoning, of the tetanic state following the injection of ptomaines, or of cholera—a disease very probably dependent upon the presence and action of a bacillus. Martin de Pedro, regarding the affection as rheumatic in character, located it in the muscles themselves, there being produced, through poisoning of the venous blood, a muscular asphyxia.

¹ Paschkie in some recent experiments found that the sulphocyanide of sodium applied in small quantities caused a tetanic state more lasting than that caused by strychnia.

² Curtiss of Chicago thought that he had found a special organism, but further investigation showed that it was present in the blood of healthy members of the family and in the water of a neighboring pond.

MORBID ANATOMY.—The pathological conditions observed upon autopsy in the wound, the nerves, the central organs, and the muscles, have been so various and inconstant that post-mortem examinations have afforded little or no definite information respecting the morbid anatomy of the disease. Many of the reported lesions have unquestionably been dependent upon cadaveric changes or defective preparation for microscopic study. The wound itself has been found on the one hand healthy and in due course of cicatrization,¹ on the other showing complete arrest of the reparative process ("the sores are dry in tetanus," wrote Aretæus),² or even gangrenous, with pus-collections, larger or smaller, in its immediate vicinity, usually in connection with retained foreign bodies.

The nerves in and about the injured area have often been found reddened and swollen, their neuroglia thickened and indurated, and blood extravasated at various points. At times, even when to the naked eye healthy, microscopic examination has shown one or a few of the constituent bundles inflamed. But repeatedly the most thorough search has failed to find any departure from the normal state, and the same appearances of congestion and inflammation are not seldom observed when there has been no tetanic complication. In an interesting case reported by Michaud the sciatic in the uninjured limb presented the same neuritic lesions as that of the wounded side.

In the cord and the medulla vascular congestion has been the condition most generally seen, associated not infrequently with hemorrhages and serous effusions—a condition occasionally absent, and when present due, it is probable, in great measure, perhaps wholly, to the muscular spasms, or consequent in part upon post-mortem gravitation of the fluids. Increase in the amount of the connective tissue of the white columns of the cord (thought by Rokitansky to be the essential lesion of the disease); disseminated patches of granular and fluid disintegration (to which Lockhart Clarke called attention in 1864); atrophy of the cells, especially those of the posterior gray commissure; nuclear proliferation; changes in the color, form, and chemical reaction of the ganglion-cells; dilatation and aneurismal swellings of the vessels, with development of granulation-masses in their walls; and changes in the sympathetic ganglia,—such have been the reported lesions. But each and every one has at times been absent—at times been discovered in the bodies of those dead of other diseases. Some of the changes have without doubt been produced after death; some perhaps have been but errors of observation.

The muscles have been found healthy in appearance and constitution; discolored, softened, and the seat of blood-extravasations large and small; undergoing the vitreous degeneration; and ruptured, the laceration affecting a few fibres or the entire thickness of one or more muscles, as the rectus abdominis, the muscles of the neck, those in the vertebral gutter, and even the heart. The rigor mortis appears at once or very soon, thus confirming Brown-Séquard's observation, that cadaveric rigidity is "quick in coming on and quick in passing off in direct proportion to the amount

¹ Of one of Hennen's cases it is reported that "the life of the patient and the perfect healing of the wound were terminated on the same day."

² Morrison seventy years ago wrote: "Wounds from which there is a copious discharge of bland pus are seldom or never followed by this disease;" and as a rule this is true.

of long-continued violent action which preceded death." The visceral congestions that have been observed cannot be regarded as in any way peculiar, but as due simply to the muscular spasms and the mode of dying.

It is probably by chemical and microscopical examinations of the blood, and, much more, the solids and fluids of the damaged part or the secretions of the skin in the non-traumatic cases, that the cause of this obscure affection is to be discovered, and not from study of the nerves, the cord, and the brain; which study up to the present time has only shown that "tetanus has no morbid anatomy, except perhaps its traumatic cause and the asphyxial congestions resulting from it."

SYMPTOMS.—Following the receipt of a wound, tetanus may be developed quickly or only after many days, cases of more or less credibility being on record of immediate appearance, and of an elapsed interval of one, two, three, even seven months (in a case occurring during our late war). Doubt, however, may very properly be entertained as to the true tetanic character of some at least of these very long-delayed cases, or of their dependence upon the previous traumatism. The very common belief that after the lapse of three weeks no fear of the disease need be entertained is unquestionably an erroneous one, but the danger certainly is slight when the wounded person has escaped for twenty-two entire days. In by far the larger proportion of cases the outbreak occurs between the fifth and fifteenth days after injury—in about two-thirds, according to Yandell's, or about four-fifths, according to Joseph Jones's and Otis's statistics.

Not infrequently for a day or two before any distinct evidences of the disease are manifested there is prodromal malaise, associated at times, but by no means constantly, with unusual sensitiveness, or even positive pain, in the wound and slight muscular twitching in its vicinity. In the larger number of cases the first symptoms noticed are stiffness about the jaw, more or less difficulty in opening the mouth, and perhaps slight interference with deglutition, the patient feeling as if he had taken cold; such symptoms often appearing early in the morning after waking from the night's sleep. With more or less rapidity well-marked trismus comes on, the jaws being locked, the corners of the mouth retracted, and the lips either firmly closed or separated so as to uncover the teeth, producing the peculiar grin long known as the *risus sardonicus*.

In rare cases it is the depressors, and not the elevators, of the lower jaw that are in a state of contraction, the mouth consequently being kept wide open. The forehead is wrinkled, the eyes staring, the nose pinched, and not seldom there is the facial expression of old age. The voice is altered and swallowing is difficult. Occasionally the spasms of the muscles of deglutition are so intense as to be the principal tetanic symptom, such dysphagic or hydrophobic (Rose) tetanus very generally proving fatal. In a few cases, after wounds of the face and head, these violent spasms have been found associated with facial paralysis, almost always, if not always, on the injured side; such paralysis having been present in at least one case (Bond's) in which throat-spasm was wanting, the wound being in the temporo-parietal region. Often there is early felt in greater or less intensity pain, as from pressure, in the epigastrium, piercing through to the back—a symptom by some regarded as pathognomonic, and due without doubt to contraction of the diaphragm.

From the region of the jaw the disease passes on to successively attack the muscles of the neck, the back, the abdomen, the chest, the lower, and, last of all, the upper, extremities, those of the forearm long after those of the arms. The muscles of the fingers, of the tongue, and those of the eyeball are very late if at all affected, the tongue probably never being tonically contracted. The anterior abdominal wall is broadened, depressed, and hard. In the fully-developed acute cases the whole body is rigid, remaining perfectly straight (*orthotonos*), arched backward (*opisthotonos*), forward (*emprosthotonos*), or laterally (*pleurosthotonos*), according as the muscular tension is balanced or greater on one side than another. The action of the extensors being usually the more powerful, backward bending (*opisthotonos*) to a greater or less extent is the ordinary condition; but only in rare and extreme cases is the contraction such as to curve the body like a bow and keep it supported upon the occiput and heels. Frequently the bending is not specially noticeable except in the neck. *Emprosthotonos* is rare, and *pleurosthotonos* has been so seldom observed that its very existence has been denied. Occasionally, in well-marked cases of *opisthotonos*, there is some associated lateral arching, due rather to voluntary efforts on the part of the patient (for the purpose of obtaining relief) than to tetanic contraction. Larrey's opinion that the location of the wound (behind, in front, or on the side) determined the direction of the curving has been proved to be incorrect. Except in a small proportion of cases to the persistent tonic spasm¹ there is added convulsive seizures of the affected muscles, developed upon any, even the slightest, peripheral excitation of the reflex irritability, as by a movement, a touch, a draft of air, a bright light, a sudden noise, an attempt at swallowing, etc. The frequency of these clonic exacerbations and their intensity vary much, being severer and coming on closer together in the grave acute cases and in the later stages of those terminating fatally. They may occur only once in several hours or four, five, or more times in a single hour, each spasm lasting from but a few seconds to a minute or two. During its continuance the suffering is intense, both from the pain of the contraction and the experienced sense of suffocation. Between the paroxysms there is usually but little pain, the sensation being rather one of tension or pressure. Occasionally cessation of spasms and complete relaxation of all muscular contraction suddenly take place six, eight, or twelve hours before death, the patient quickly passing into a state of collapse.

Throughout the whole course of the disease the mind remains clear,² except in the later stages of a few cases; and then the existing delirium or coma is often, it is probable, an effect of the treatment that has been employed. Except in the more chronic cases the patient is generally unable to sleep, and even when fortunate enough to do so the tonic spasm may not relax. In other than the mildest attacks there is usually noticed a marked increase, local or general, of the perspiration; such sweating

¹ This is not, in reality, a state of uninterrupted spasm, but one of very numerous, quickly-repeated muscular contractions, as many even as six hundred and sixty per minute (Richelot).

² "The brain alone in this general invasion has appeared to us to constantly preserve the integrity of its functions down to the very last moment of existence, so that the unfortunate subject of this disease is, as it were, an eye-witness of his own death" (Larrey).

being a much more prominent symptom of the disease as met with in tropical than in temperate regions.

The pulse, which is normal in the earlier stages, may later be but little increased in frequency (except during the exacerbations, when, small and compressible, its beats may run up to 140, 160, or even 180 per minute), or it may become progressively feebler and more rapid as the case advances toward the fatal termination. The irregularity often noticed during the convulsive seizures is doubtless owing to the muscular contractions so compressing the vessels as to hinder the passage of the blood through them. That the heart itself is not tetanically contracted would seem to be proved by its regular quiet action during anæsthesia.

The body-heat varies greatly in different cases, the temperature being oftentimes normal, or even subnormal, until toward the very last. Not infrequently, even in severe and fatal cases, it is not increased more than two or three degrees, and quite rarely, except just before death, does it rise much above 103° F. Exceptionally, very high temperatures have been observed; I have myself seen one of 108° F. an hour before death. Prévost had a patient whose axillary temperature was $110\frac{3}{4}^{\circ}$ F. Lehmann reports a heat of 111.9° F. just before death, and in one of Wunderlich's cases the temperature (that three hours earlier was 103.5° F.) fifteen minutes before death was 110.1° F., and at death 112.5° F., with a further post-mortem rise of more than a degree ($113\frac{3}{4}^{\circ}$ F.)—a phenomenon that has been observed in a number of cases. This increased temperature of tetanus is not of inflammatory origin (except as a part of it, at times, may be due to intercurrent affections, especially a bronchopneumonia), but depends doubtless upon a combination of causes, among them the violent muscular spasms, and, more particularly, the disturbance of the regulating heat-centre or centres from the alterations of their blood-supply in quantity and quality.

The bowels are usually constipated, because of the little food taken, the profuse sweating, the tonic spasms of the abdominal muscles, and the contraction of the external sphincter and the levator ani, the muscular coat of the bowel, like all the other involuntary muscles, remaining unaffected.

Micturition, generally infrequent because of scanty secretion, may or may not be disturbed. In many cases it is true, as written by Aretæus, "the urine is retained so as to induce strong dysuria, or passes spontaneously from contraction of the bladder," though it is the external muscles, and not the bladder itself, the contraction of which produces the retention or the discharge; which latter is of rare occurrence.

DIAGNOSIS.—When fully developed, with all its characteristic symptoms present, tetanus cannot, or at least ought not to, be mistaken for anything else; yet a study of reported cases will show that errors of diagnosis have been made, and because of such errors various methods of treatment have been given undue credit as curative measures. Wound-spasms, clonic in character, of different degrees of severity, beginning in and confined to the muscles of the injured part or limb (even of the lower segment of the upper extremity), have not seldom been regarded as tetanic, which they certainly are not; and recovery having taken place, it has been attributed to the adopted treatment, operative or therapeutic. The comparatively few cases in which, primarily located in the vicinity

of the wound, these traumatic spasms have become generalized in strict accordance with Pflüger's laws, or, much more rarely, passing over the intervening parts of the body, have seized upon the muscles of the jaw and neck, may perhaps, for want of accurate knowledge of the essential nature of tetanus, be regarded as a variety of the disease; but it is much to be regretted that observers and reporters have not clearly separated them from the cases of true tetanus (or the commonly met-with variety of tetanus) in which the first or first important symptoms are always in connection with the muscles whose nerves take origin in the medulla oblongata, no matter where the wound may be located or whether there is any wound at all. Not a few of the idiopathic cases may justly be regarded as of tetany, that "little tetanus" in which the spasms always proceed from the periphery toward the centre; are especially likely to affect the forearms and the fingers, forming in their contractions the obstetrical hand; are followed by periods of complete relaxation; can be brought on by compression of the main artery or nerve of the limb, or by light tapping of the affected area; may cause a rigid state of the trunkal muscles or even well-marked opisthotonos; are associated with impairment or paralysis of sensation; may last for a few minutes or for hours; and sooner or later spontaneously cease, a fatal termination of the affection being exceedingly rare.

Hysterical spasms may strongly simulate those of tetanus, and such attacks have without doubt been wrongly diagnosticated, the cases going to swell the number of those successfully treated by one remedy or another. They ought, however, to be readily recognized if due consideration be had of the age and character of the patients, the history of the attack, and the order and nature of the symptoms themselves, especially their frequent limitation to one member (preferably a leg), the absence of consciousness during the attacks, the long and uninterrupted rest at night, their more or less often and prolonged complete intermissions.

Cerebro-spinal meningitis, because of the developed stiffness of the neck and retraction of the head, the orthotonos, or even well-marked opisthotonos, the epigastric pressure-pain, the occasional trismus, and rigidity with reflex convulsive movements of the muscles of the extremities, may, and doubtless has been, mistaken for tetanus; but its generally epidemic prevalence, the headache, the cutaneous hyperæsthesia, the temperature, and the other well-known symptoms of the disease ought to suffice for its ready determination.

Strychnia-poisoning has many symptoms in common with tetanus, but there is an absence of the wound which is generally associated with the latter affection, a much more rapid development of severe convulsions, and a quickly-appearing opisthotonos. The spasms from the commencement affect the extremities, producing early contractions of the muscles of the hands and feet, and only later those of the jaw. Complete intermissions of greater or less length usually occur, and either death or marked amelioration of pain and spasm follows in a comparatively short time.

Hydrophobia, the dysphagic symptoms of which are like those at times observed in tetanus, has its peculiar wound of origin and protracted period of incubation, its absence of trismus or general tonic muscular contractions, its usual dread of water and inability to swallow fluids, its attendant restlessness, and its frequently-observed delirium, the entire

aggregation of symptoms being characteristic of itself and nothing else except the simulating nervous affections occasionally developed in individuals bitten by rabid or supposed rabid animals.

PROGNOSIS.—As declared by Hippocrates, “the spasm that comes on after the receipt of a wound is a frequent cause of death.” Violent acute cases, developing early, are excessively dangerous; and there is much truth in Poland’s declaration that “there is scarcely a well-authenticated instance of recovery on record.” Taking all the traumatic cases together as met with in military and civil hospitals, the death-rate may safely be placed at not less than 80 per cent. Of 1332 cases reported from the wars of the last thirty years, and occurring in six large hospitals during the last twenty years, 1060 proved fatal—*i. e.* 79.6 per cent.¹

As met with in private practice, under favorable hygienic surroundings, a decidedly larger percentage of recoveries probably takes place—how much larger cannot be even approximately determined, since, as a rule, only those cases which get well are reported, but few patients come under the care of any single observer, and the chances of error in diagnosis are much greater than in a large general hospital. The mortality-rate of the idiopathic cases is very much lower (not exceeding perhaps 25 or 30 per cent.), localized trismus being “never mortal, though it may last for a number of weeks” (Poncet). That recovery should take place much more frequently in cases of this variety than in those associated with wounds might be anticipated, since, as a rule, they are more chronic in their course; the attacks are less frequent; if generalized, the spasms do not involve all the muscles at once, but by progressive seizures and relaxations; and they less often and less severely affect the muscles of respiration. The earlier the disease shows itself after the receipt of a wound (other things being equal), the stronger the likelihood of a fatal termination; and, for obvious reasons, the more powerful, more general, and more quickly repeated the spasms, the greater is the danger. The larger part of the deaths occur within the first week, a majority by the fifth day; all experience tends to show that there was much truth in the Hippocratic observation, that “such persons as are seized with tetanus die within four days, or if they pass these they recover.” From the end of the first week on, the chances of recovery rapidly increase day by day, and after the second week there is but little danger of a fatal termination, though death may take place (from exhaustion usually) after the lapse of several weeks, six or more.² I have myself seen it occur on the thirty-seventh day.

¹ Crimean war, 23—21, 91 per cent.; Confederate army, (Sorrel), 66—60, 91 per cent.; U. S. army, 505—451, 89.3 per cent.; Italian war (Demme and Chenu), 176—162, 91 per cent.; Franco-German war (Poncet), 316—181, 57.28 per cent. (omitting Richter’s 224 cases with only 107 deaths, the mortality of the remaining 92 cases (74) was 80 per cent.); St. Thomas’s Hospital, 43—24, 55.8 per cent.; St. George’s Hospital, 30—21, 70 per cent.; St. Bartholomew’s Hospital, 63—47, 74.6 per cent.; Guy’s Hospital, 60—51, 85 per cent.; Pennsylvania Hospital, 26—20, 76.9 per cent.; Boston City Hospital, 24—22, 91.6 per cent. The mortality-rate at Guy’s (85 per cent.) is almost the same as that given by Poland for the period from 1825 to 1858 (86.1 per cent.).

² Of the 358 cases reported in the *Medical and Surgical History of the War of the Rebellion*, the duration of which was known, 64.8 per cent. died within five, and 83.5 per cent. within ten, days. Of 327 cases reported by Poland and Hulke, 56 per cent. died within the earlier, and 83.5 per cent. the later, period. Of Richter’s cases, 76.6 per cent. died within five days. Of 170 cases tabulated by Yandell, 53 per cent. died within the first four days, and 77 per cent. within nine days.

Recovery is usually slow. Even in the non-traumatic cases the period of convalescence very seldom is less than two months, and, as has been truly said, "it is a very mild case that the patient is well of in thirty days." More or less stiffness of the muscles usually continues for many weeks; in one case (Currie's) "his features retained the indelible impression of the disease;" and Copland reports having seen a man who had had tetanus nine years before, whose jaws were still permanently locked. Relapses may easily be brought on by exposure or slight imprudences, and such secondary attacks not infrequently prove fatal. The earlier and more severely dysphagic symptoms are manifested, the more grave the prognosis; and the sooner disturbances of respiration are shown, the speedier the death, since spasm of the respiratory muscles, in the words of Aretæus, "readily frees the patient from life." Generally stated, "the more powerful the contractions, the greater the irritation and the danger;" and the longer the delay of involvement of the respiratory muscles, the more favorable the prognosis. The occurrence of strabismus is of grave import (Wunderlich), as might be expected, since only in very severe cases or in the later hours are the deep muscles of the eye affected by spasm. The manifestation of delirium (which is rare, and sometimes, if not generally, due to over-medication) indicates with almost absolute certainty a speedy death.

The pulse-rate and temperature, especially the latter, afford prognostic indications of value.

A rapid pulse is an unfavorable symptom; and if at the same time it is feeble and irregular, the probabilities of an early death are very great.¹ Though, as has already been stated, the temperature often varies but slightly from the normal, even in acute and rapidly fatal cases, yet when the thermometer does not indicate a body-heat of over 100° F. the prognosis is unquestionably more favorable than when it is two or more degrees higher; and there is certainly much truth in the opinion (Arloing and Tripier) that as long as the rectal temperature is not above 100 $\frac{2}{3}$ ° F. (38° C.) the prognosis is favorable; whereas when it rises the prognosis at once becomes much more grave, few patients recovering in whom it reaches 103° F. Oscillations of temperature are of no prognostic value, good or bad.

Death usually occurs suddenly, from spasm of the external respiratory muscles or of those of the larynx, but it may be consequent upon a slow strangulation, upon exhaustion (as it frequently is in the chronic cases), or even upon heart rupture, as in a patient of Dujardin-Beaumetz.

How far the age of the patient affects the prognosis cannot be very definitely stated. The prevalent opinion (entertained as long ago as the time of Aretæus), that the disease is less dangerous in the middle part of life than as either extreme is approached, is probably an erroneous one. Yandell, from the analysis of the cases he had collected, found that the mortality was greatest in children under ten, and least in individuals between ten and twenty years old. Kane's statistics would place the time of greatest danger in the early adult period, from the age of twenty to that of thirty-five or forty.

¹ Few at the present time share Parry's belief, that "if in an adult the pulse by the fourth or fifth day does not reach 100 or perhaps 110 beats in a minute the patient almost always recovers," and "if, on the other hand, the pulse on the first day is 120 or more in a minute, few instances will be found in which he will not die."

In traumatic cases the location of the wound does not seem to materially influence the death-rate. As occurring during our late war, those associated with injuries of the upper extremity were the least, and of the head, face, and neck the most, fatal, but the difference in the mortality-rates was but 8.4 per cent. (86.8 : 95.2 per cent.). It has long been believed that wounds of parts supplied by the cranial nerves are not only less often followed by tetanus than those of other regions, but that the disease when present is of a less fatal character. Of the 10 cases of the peculiar head-tetanus already referred to, collected by Bernhardt, 6 died (60 per cent.).

TREATMENT.—For the relief of tetanus agents of most diverse action and power have been employed, intended to control inflammation, allay nervous irritability, arrest spasm, and sustain the general strength; and operations have been performed with the view to destroy nerve-conduction, remove external irritants, change the character of the associated wound, or take away the originally damaged part. Much of the confusion and uncertainty that have prevailed respecting the therapeutic treatment has doubtless arisen from the want of distinct separation of the idiopathic from the traumatic cases, because of incorrect diagnosis, or through an unwarranted assumption of the general applicability of a method of medication found advantageous in individual cases of perhaps rheumatic, malarial, or meningeal disease.

Regarding the affection as inflammatory, the older surgeons treated it antiphlogistically, and until within comparatively recent times bloodletting and mercury were largely employed. General and local bleedings, resorted to as far back as the time of Hippocrates, were not seldom made in excessive amounts,¹ the patient occasionally surviving both the disease and the treatment. The mercurials were pushed until profuse ptialism was produced—a condition which could but add to the distress (because of the great difficulty experienced in clearing the throat and mouth), and likely to induce and increase the severity of the convulsive seizures. Combined with opium, calomel was formerly held in high repute, and numerous recoveries have been attributed to such treatment—recoveries, however, almost always of cases of chronic character and no great severity. Should the mycotic origin of the disease ever be demonstrated, there will be good reason, in its well-known destructive action upon minute organisms, for the administration of the mild or corrosive chloride of mercury. Cold baths and affusions have sometimes caused entire relaxation of the spasms, leaving the patient as supple as a glove, and not seldom have been followed by muscular ruptures or sudden death.² The local application of ice to the spine has been credited with many cures, particularly of cases of the non-traumatic variety, and benefit has seemed to follow the employment of ether or rhigoline spray. Hot baths, water

¹ In a case of Lisfranc's, in twenty-six days venesection was made nineteen times, and seven hundred and seventy-two leeches were applied.

² An interesting and frequently-mentioned case is reported by Sir James McGrigor. A soldier having tetanus (unusually severe) was "during the first part of the day drenched with rain, the thermometer standing at 52°, but after ascending one of the highest mountains in Galicia the snow was knee-deep and the thermometer below 30°. The patient was exposed to this inclement weather from six o'clock in the morning till ten at night, when he arrived half starved to death, but perfectly free from every symptom of tetanus."

or air, general or local, have been largely used from the time of Paré down, and the induced free perspiration has in some instances seemed to have been of service, as have the medicinal agents acting as sudorifics, of which jaborandi has of late been the one ordinarily employed. "To relieve the contractions and provoke sweating are the two principal bases of treatment," wrote Martin de Pedro. But it should not be forgotten that in many of the more severe and rapidly-fatal attacks profuse sweating is characteristic of the disease.

All violent depleting measures should be abstained from, since in the acute attacks they can do no good, and in the more chronic ones can only increase the general debility; and it is from exhaustion that the subjects of these latter usually die.

To lessen the reflex irritability, to quiet the muscular spasms, and support the patient are the prime indications; to fulfil which every agent in the *materia medica* that has, or has been supposed to have, any sedative action upon the nervous system has been employed, as well as remedies directly controlling muscular movements. Of the greater number of such it may be truly said, "They have the same value, and the best of them is good for nothing" (Giraldes).

At the present time the medicinal agents that are deserving of consideration are tobacco, the anæsthetics, curare, conium, cannabis indica, calabar, opium, chloral, and the bromides.

Tobacco, that in virtue of its depressant action so powerfully relaxes the muscles, was until the introduction of the anæsthetics largely employed and regarded with much favor, but of late years has rarely been used, inhalations of chloroform or ether securing more rapid and complete relaxation, with far less danger to the patient. Nicotine, in doses of from a fraction of a minim to a full minim ($\frac{6}{10}$ gr.) by the mouth, or two by the rectum (Houghton), has been given instead of the tobacco infusions with equally good effects, and of course the same dangers of producing fatal collapse.

The anæsthetics, chloroform and ether, have been frequently administered, but although muscular relaxation and sleep have been thereby secured, the natural progress of the disease toward a fatal termination has not been materially affected: death has at times been directly and suddenly produced, and not infrequently, though the inhalations have lessened suffering, they have seemed to hasten the end.

Curare, which "powerfully impairs and destroys the conductivity of motor nerves," and of which, consequently, much was hoped at one time, has proved to be of but little value.¹ In order that benefit may follow its administration the agent must be given in large doses and until a decided impression is made upon the innervation of the muscles of respiration, great danger meanwhile existing of producing asphyxia, for the relief of which artificial respiration must be instituted. McArdle of Dublin, in reporting recently a successful case of the acute variety in which gr. $\frac{2}{3}$ was given every fifth hour, suggested the combination of curare and pilocarpine, "in the hope that the cardiac and respiratory trouble produced by the former might be prevented by the latter." Uncertain in composition, cumulative in action, "dangerous, difficult to manage,

¹ Of Demme's 22 cases, 14 died (63.6 per cent.); of Busch's 11 cases, 6 died (54.5 per cent.); and in 51 cases collected by Knecht the mortality-rate was 49 per cent.

and variable in its effects," curare is not, so far as has as yet been determined, an agent to be recommended in the treatment of tetanus.

Conium, the action of which is much akin to that of curare, and which primarily is upon the terminal portions of the motor nerves, has been occasionally employed—successfully in two cases by Christopher Johnson of Baltimore, who gave it hypodermically in doses of from $\frac{1}{8}$ to 2 minims every one, two, or three hours. In two other cases under the care of the same surgeon death took place, but the remedy seemed to have acted beneficially in relieving the spasms and relaxing the tonic rigidity.

Calabar bean—which produces a paralyzing action on the spinal cord, abolishing its reflex functions, and later "diminishes and destroys the conductivity of the motor nerves"—though apparently of service in certain cases (almost all of them, however, in young subjects and of chronic character), has proved to be of little or no more value than other less dangerous agents. It was first clinically employed by Vella in the Italian war of 1859. Of the 39 cases in Yandell's table, 39 per cent. recovered; of the 60 in Knecht's, 45 per cent.; and of the 60 collected by H. C. Wood, 55 per cent. It may be administered by the mouth, the rectum, or subcutaneously in doses (of the extract) of from $\frac{1}{8}$ gr. to 2 grs. every quarter hour, half hour, hour, or two hours (Ringer gave 4 grs. in an hour),¹ according to the violence of the symptoms, being stopped when there is produced "vomiting, diarrhœa, or a rapid small pulse and clammy sweat." Yet its beneficial action in severe cases is only manifested when it has been "pushed to the extent of rendering the patient collapsed, the temperature of his body falling perhaps to 94° or 95° F., the pulse being hardly perceptible at the wrist" (Macnamara); under which circumstances there is about as great risk of death from the treatment as from the disease itself. Always, fever is a contraindication to its employment.

Cannabis indica, originally used by the East Indian surgeons, and believed by them to have a powerful influence in controlling the tetanic spasms, has proved much less efficacious in cases occurring in Europe and this country, perhaps because of the unreliable character of the extract used; though of 42 cases of the traumatic variety treated in the Channie Hospital at Calcutta in five years (1865–69), 62 per cent., and of 39 idiopathic cases 40 per cent., died, and of Chuckerbutty's 13 cases in India, 6 (*i. e.* 46 per cent.) died. Of the 25 cases in Yandell's table, the mortality-rate was 36 per cent. If given, it should be in doses of from $\frac{1}{2}$ to 2, or even 4, grs. of the extract, or ℥15 to 3j of the tincture, every two or three hours. Having a strong hypnotic action, it is to this probably that the beneficial effects of its administration are due, rather than to its secondary influence upon sensation and muscular movements.

Of all the sedatives and narcotics, opium has been longest and most often used, and in so far as it relieves pain and causes sleep it is of service. Like the other agents, it must be administered in large doses, reference being had to the effect produced and not to the number of grains given. The difficulty of swallowing even the liquid preparations has of late years made the hypodermic injections of morphia the favorite mode of administering the drug. Demarquay has advised that the solution (1 part to 50 of water) should be thrown deeply into the substance

¹ E. Watson gave to a patient in the course of forty-three days the equivalent of 1026 grs. of the solid extract, a tincture of the powdered bean being largely employed.

of the affected muscles, as near as possible to the place of entrance of their supplying nerves; the result being to especially relieve the trismus and allow of the taking of food. Fayrer in India found opium-smoking of advantage. The mortality-rate of the 185 cases tabulated by Yandell treated with opium was 43 per cent., but, as is true of the other drugs that have been referred to, it is chiefly if not wholly in the mild and chronic cases that the beneficial effects have been observed.

So far as has yet been determined, chloral is our most valuable drug in the treatment of tetanus, as it is in that of the allied condition of strychnia-poisoning—not because of any direct antidotal action, but by reason of its producing sleep, lessening the reflex irritability of the spinal cord, and diminishing the violence and frequency of the muscular spasms, thus enabling the patient to keep alive until the morbid state can spontaneously disappear. Given usually by the mouth or the rectum, it has been administered hypodermically (as much as 5 grs. at a time by Salter) or, as proposed by Oré, thrown directly into a vein. If it is true, as has been claimed, that its beneficial effect is due entirely to the sleep secured (not infrequently after waking up the spasms return with increased violence), the drug should be administered in doses sufficiently large and repeated to maintain a continuous slumber. Verneuil (whose therapeutic formula has three terms, rest, warmth, sleep) has found that while with certain patients a drachm a day is enough, to others four times as much must be given, and directs that the chloralic coma be continued for about twenty days. Further experience may show that small doses may suffice to secure the needed quiet—as, *e. g.*, the 40 grs. at bedtime, with, if necessary, 30 grs. more at midday, recommended by Macnamara. Such small doses are far safer than the enormous ones that have at times been employed,¹ since chloral can exert a powerful toxic influence upon the circulatory and respiratory centres, death being almost always due to arrest of respiration, though in tetanic cases it may be the effect of slight spasm upon a heart the enfeebled state of which is indicated by a very rapid and thready pulse. The intravenous injections expose the patient further to the risk of the formation of clots and plugging of the pulmonary artery, several instances of which accident have already been reported, though this method of treatment has but seldom been employed. The death-rate of those treated by chloral alone was 41 per cent. in the 134 cases analyzed by Knecht, and 41.3 per cent. of the 228 tabulated by Kane.

Of late years use has been made, either alone or in combination with opium or chloral, of the bromides, especially that of potassium, which in full dose unquestionably diminishes reflex irritability, lessens the sensibility of the peripheral nerves, and moderates excessive body-heat. Under its influence mild cases of tetanus have recovered and more severe ones been somewhat relieved, and it has the decided advantage over the other drugs that have been noticed of not being a direct cause of death even when given in large dose—as much in some instances as six, seven, or nearly eight drachms a day. Knecht found that of 10

¹ Beck is reported to have given 420 grs. in three and a half hours, and Carruthers 1140 grs. in six days; both patients recovered—Beck's after a continuous sleep of thirty hours. In one case the chloral sleep was maintained without interruption for eight days, from 250 to 300 grains a day being given; and in another, which also recovered, over 3000 grs. were taken in the course of thirty-eight days.

cases treated with chloral and the bromide, 9 got well; and Kane, of 21 to whom such a combination was given, only 5 died (23.8 per cent.); but the number of cases is too small to make conclusions deduced therefrom of any special value. Voisin reports a case (in which it should be noted the spasms began in parts near the wound, and that on the fourteenth day after the receipt of the gunshot injury of the right thigh) that had for eleven days been treated without effect with chloral in large quantity, which at the end of that time was put upon 3ij doses of the bromide, with three hypodermics a day of about $\frac{1}{2}$ gr. of morphia each: in three days decided improvement had taken place, and in four days more the patient was well.

The sedative and sustaining action of alcohol has many times been taken advantage of in the treatment of this affection. The administration of wines or spirits in large amounts has certainly been found of much service, though it will seldom or never be necessary to give wine, as Rush advised, "in quarts, and even gallons, daily." 80 per cent. of recoveries appear to have taken place in the 33 cases that Yandell found to have been treated with stimulants; but, on the other hand, of Poland's 15 cases treated with wine, 75 per cent. died: here, again, the numbers are too few to make any deduced conclusions of much value.

As tetanus (or at least tetanoid spasm) has at times been observed as a consequence of malarial poisoning, and successfully treated with quinine, this remedy has occasionally been employed in cases not dependent upon paludism, but very generally to no purpose.

Fowler's solution of arsenic in doses of from 5 to 20 minims every two, three, or four hours has been believed by certain of our American surgeons (Hodgen, Prewitt, Byrd) to be of service.

Because of the supposed origin of the disease in peripheral nerve-inflammation or irritation, operative procedures have many times been adopted to interrupt the conduction or remove the part.

Amputation, which was so highly commended by Larrey, is now recognized as of no service in the severer and more acute cases, and as unnecessary mutilations in the chronic ones; and if performed in those of intermediate severity, when recovery takes place it will generally be difficult or impossible to determine of how much benefit the operation really was, and in some at least of the fatal cases the result can fairly be attributed to the amputation itself. When the disease is associated with an extensive lesion of an extremity, there can be no objection to the removal of the damaged part (if performed early), except that it may by the added shock still further weaken the patient and render him less able to hold out against the tetanus. In cases of severe spasms limited to the muscles of the injured limb (and such are frequently said to be of tetanus) amputation is often strongly indicated, and not seldom is the only treatment that will afford relief. During our late war "amputation was resorted to in 29 instances after incipient tetanic symptoms; 10 of the cases resulted favorably, and in several instances it is noted that the symptoms ceased after the operation."¹ Of Yandell's 17 cases, 60 per cent. recovered.

¹ *Medical and Surgical History of the War of the Rebellion.*

As there is here, apparently, recovery in 34.5 per cent. of the gunshot cases treated by amputation (nearly one-fifth of all the non-fatal cases reported)—a very gratifying degree of success, and one that might properly encourage the resorting to this method of

Nerve-section, first made by Hicks in 1797, and nerve-stretching, first performed by Vogt in 1867—reason for which can be found only in the neuritis (or, much more strongly, the reflex-neurosis) theory of the disease—has not been followed by relief in any unusually large proportion of cases,¹ and should be practised only when the affected nerve is clearly indicated, when there is much pain in the wound, or when a distinct aura proceeds therefrom. In determining what nerve shall be divided or stretched regard may with advantage be had to Wood's symptom—to wit, the development of pain when pressure is made upon the nerve-trunk, branches from which terminate in the wound.

Arloing and Tripièr strongly advised total neurotomy (*i. e.* division of all the nerves going to the damaged part), and that high up—an operation that must be followed by extensive paralysis; not, however, permanent, they claim; in six months, at the latest, the power of motion being regained. This period is altogether too limited, as has been proved more than once. Fayrer reports having seen a case in which the hand was permanently crippled. It is to be noted that in most of these nerve-operation cases that terminate in recovery the tetanic spasms in the other parts of the body do not cease at once, but often quite slowly, and in the

treatment—somewhat careful analysis may well be made of the 7 cases the histories of which are given. In 2, shell wounds of the foot, operated upon by the same surgeon, the disease appeared while the men were still upon the field. Of one of them it is stated that "there was but little hemorrhage, but the shock was excessive and tetanic symptoms were present;" and of the other, that "the peculiarities in the case were that symptoms of tetanus were quite marked, with great exhaustion." There are certainly good reasons for believing that these two cases were not of tetanus, but of simple convulsive movements from shock and anæmia. Of the remaining 5 cases, the symptoms manifested themselves on the fourteenth, nineteenth, twenty-first, thirty-fifth, and fifty-fourth day after the receipt of the wound. One of the patients (in whom the disease was longest delayed), having a much inflamed and suppurating compound fracture of the bones of the forearm, "was suddenly seized with a chill followed by threatening tetanus," and amputation was made the following day. In another (thirty-fifth day case) the "arm became much swollen and symptoms of tetanus ensued, including stiffening of the jaws, great pain and restlessness, and irritable pulse;" two days later the limb was removed, and "all symptoms of tetanus disappeared after the operation." In another (twenty-first day) the man when admitted into hospital, one month after the date of the injury, stated that "he was first taken with trismus about a week before." "As he was certainly getting worse every day," the forearm was removed forty days after the receipt of the wound and nearly three weeks after the commencement of the tetanic symptoms. Other remedies employed after the operation (brandy, chloroform, and blisters to the spine) doing no good, 3ss doses of the tr. cannabis indica were given every two hours, "under which the patient slowly improved." In another case (nineteen days) the symptoms were those of tetanus; the amputation was made on the following day; twenty-four hours later "rigidity of the muscles had partly disappeared, and improvement continued until the patient was entirely relieved." In the remaining case (fourteen days) the first symptoms of tetanus "were relieved by active purgatives, calomel, etc. Three days later the symptoms returned," and on the next day "tetanus supervened in its usual form." Five days afterward "the leg was amputated at the middle third, after which the tetanus subsided and the patient made a rapid and good recovery."

In all of these five cases the disease appeared so long after the receipt of the wound that the chances were that if it was tetanus recovery would take place without regard to the treatment adopted; and of two some doubt may properly be entertained as to their real nature, there being present in both much inflammation—in one an initial chill, and in the other restlessness, great pain, and an irritable pulse. If the unpublished histories of the other three cases are similar to those given, these reported ten successful amputations can affect but little, or not at all, the previously entertained opinion of the real value of this method of treatment—that it is destructive to part, dangerous to life, and only very exceptionally, if ever, curative of the disease.

¹Of section, 21 cases, 10 deaths—*i. e.* 47 per cent. (Poncet); of stretching, 46 cases, 36 deaths—*i. e.* 78.2 per cent. (Harte).

larger number of them internal medication of some kind is steadily employed. The removal of foreign bodies from the wound, the freeing of nerves from constricting ligatures, the division of the parts around containing nerve-fibres, and cauterization of the unhealed surface—each has at times proved beneficial, and the first two should always be early resorted to if the necessity therefor exists, no matter what views may be entertained respecting the nature and cause of the disease.

Tracheotomy, first proposed by Physick and later advised by Marshall Hall, has rarely proved of service, since the dyspnœa generally depends upon causes other than spasm of the laryngeal muscles. Verneuil, however, has recently stated that he has saved several lives by this operation.

Careful analysis of reported cases clearly indicates that neither in drug nor operation has a cure for tetanus as yet been found. Almost without exception "in the fully-developed cases all remedial measures fail, and the cases run on unchecked to a fatal termination;" and with the subjects of such acute attacks the physician, in the words of Aretæus, "can merely sympathize." If not quickly overpowered by the violence of the seizure, and if he can be sufficiently supported, the patient may recover; and if there is late appearance, slow development, and infrequent and limited spasms, he probably will do so, whatever may be the treatment adopted.

"The first indication," wrote John Hunter, "should be to strengthen the system;" and in the fulfilment of this indication food is of prime importance:¹ "many patients perish from too much medication and too little feeding" (Agnew). Stimulants and hypnotics indirectly yet powerfully sustain the strength, and the removal of sensory irritants, as light and noise, by lessening the frequency of the spasms contributes to the production of the desired result, since in the convulsed muscles themselves there are developed substances that cause contraction. "Quiet and warmth are indispensable." Fœcal accumulations can but irritate, and therefore an early action through enema or mild drug should, if possible, be secured. As has been happily said by Labbé, "one must treat the tetanics, not tetanus."

If little can be done to cure, much can be done to prevent. The influence of predisposing causes (anxiety, care, excesses, paludism) is to be counteracted as far as may be; the hygienic surroundings of the wounded are to be rendered as favorable as possible; especially is proper ventilation to be secured, and exposure to cold and rain avoided. Whether or not one believes with Rose that the disease depends not on the kind of wound, but on its treatment ("the earlier it is treated in the most careful manner the less frequently do we have tetanus"), there can be no question as to the great advantage to be derived from the thorough cleansing of the wound, the removal of irritating foreign bodies, the securing of free drainage, and the lessening of the amount of inflamed and dying tissue. The marked diminution in the number of cases observed in the last thirty years, as compared with that of a century or three-quarters of a century ago, is the direct result, we may well believe, of improved treatment of wounds and the wounded. The greater danger of slight injuries very possibly lies in their liability to be neglected or mistreated,

¹ If necessary, fluids may be administered by means of a tube passed through the nose, or given by the rectum.

and the special gravity of punctured wounds of the hand and foot in the anatomical obstacles presented to the ready outflow of blood, serum, or pus. In the exceedingly fatal toy-pistol wounds is it not in the decomposing debris of the lacerated tissues, or in the retained wad saturated with the secretions, that the danger lies of the development of tetanus, and not in nerve-irritation or any peculiar character of the injury? Certainly in the only case I have myself seen, in which the disease was not developed, the damaged hand was kept under hot water from the time it was hurt until healing was complete, and free drainage was from the first maintained.

Tetanus is reported to have appeared notwithstanding the associated injury was antiseptically dressed; but in modern wound-treatment, with its cleanliness, its protection of the damaged part, its infrequent manipulations, and its power to diminish inflammation and prevent decomposition, lies, we may well believe, the means of reducing to a minimum the danger of occurrence of those spasms that, once developed, are of "exceedingly painful nature, very swift to prove fatal, but not easy to be removed" (Aretæus).

Puerperal Tetanus.

As met with after abortion or labor at term, tetanus presents no special peculiarities in course, treatment, or termination. Of very rare occurrence in temperate regions, it is often met with in hot countries in women of the darker-colored races. Grief, anxiety, overwork, and profuse hemorrhage predispose to it, as do obstetrical operations and the retention of pieces of the placenta. Unlike the ordinary puerperal affections, it is more common in the country and in private practice than in cities and hospitals. Rather elderly women are more often attacked than are those younger. First and second pregnancies are the more dangerous if completed; later ones if abortion occurs. Abortion in the earlier months, especially in the third, is most likely to be followed by the disease (Garrigues). Ordinarily manifesting itself within ten days after labor, it has been known to occur after an interval of a month.

Hysteria, eclampsia, and especially tetany, may be mistaken for it. The latter affection, which generally attacks young women, may occur at any time during pregnancy or lactation—tetanus only within a comparatively few days after delivery.

Its TREATMENT is the same as that of ordinary tetanus, care being taken to remove from the uterus as speedily as possible any contained foreign body. Antiseptic irrigations may prove of service, though it is doubtful if their employment can accomplish much after the commencement of the spasms. Aveling has thought that transfusion might perhaps be of benefit.

The occurrence of intracranial congestions, hemorrhages, and venous thrombosis¹ will, almost of necessity, render any medication of no value.

Under all circumstances the PROGNOSIS is exceedingly grave. The

¹Such as were found upon autopsy in the case reported by Macdonald, and believed by him to be the essential lesions of the disease.

mortality-rate of the cases after abortion collected by Garrigues was 92 per cent. (25-23), and of those after labor 84.37 per cent. (32-27).¹

Tetanus Neonatorum.

From the earliest times it has been known that newly-born children are occasionally the subjects of trismus and generalized spasms, and that those thus affected usually die.

More common among the darker races² and in warm countries (though some of the southern races and tribes are almost or altogether free from it), it has been for years together endemic in places far north (*e. g.* the islands of Heimacy and St. Kilda), and a veritable scourge in certain lying-in hospitals (*e. g.* Dublin, Stockholm, St. Petersburg). Occasionally it has prevailed epidemically.

Attacking usually the children of the poor, others have not been altogether exempt from it, though unquestionably "it is most often seen where the mothers of the children are very young or very poor or very worthless" (Mosely). Rarely appearing before the third day, it as rarely occurs after the twelfth, generally manifesting itself within the first week.

Its cause has been thought to be navel-string injuries; inflammation of the umbilical arteries or vein; reflected irritation from the skin, the bowels, or the external genitals; uræmic encephalopathy; cold and dampness; defective ventilation; and indirect pressure upon the cerebellum and the medulla.

The supposed causative umbilical lesions have time and again been found in young infants presenting none of the symptoms of the disease; and the same is true of the vessel inflammations³ and of the reflex irritations. Atmospheric and climatic states and the hygienic condition of the child and its surroundings, however much they may contribute to the development of the affection, cannot be regarded as directly producing it; though experience has shown (as in the lying-in hospitals before referred to) that by securing proper care of the children, by improving the ventilation, and by preventing overcrowding, its prevalence may be very greatly diminished.

Forty years ago Marion Sims believed that he had discovered the exciting cause in "pressure exerted on the medulla oblongata and its nerves, the result most generally of an inward displacement of the occipital bone," occasionally, though rarely, of the parietal. That intracranial pressure may give rise to tetanic symptoms is beyond question, seizures identical with those of tetanus having been observed in connection with tumors of the cerebellum (Hughlings Jackson), as also trismus, confined even to one side (Wernicke).

¹ As indicating the extreme gravity of tetanus occurring in connection with a wound of the genital tract, it may be noticed that of 17 cases after ovariectomy collected by Parvin, 16 died, 94.1 per cent., and of 24 cases tabulated by Olshausen, 23 died, 95.83 per cent.

² Wallace, however, found that in the Medical College Hospital at Calcutta the disease occurred proportionably more frequently in the children of European than of native mothers, though the actual number of cases among the latter was very much the greater.

³ Mildner of Prague reports that in 46 fatal cases of inflammation of the umbilical vein, convulsions occurred in but 5, and in these the spasms were not like those of tetanus.

In some cases without doubt the occipital depression is secondary, the result of intracranial shrinkage; and even if primary, there may be no lockjaw.¹

Parrot regarded the disease as a form of eclampsia, the uræmic encephalopathy manifesting itself as one or other of the three varieties recognized (by Cederschjöld) a half century ago—viz. trismus, tetanus, and ordinary eclampsia. The articular rigidity, especially noticeable in the temporo-maxillary joint, he held to be largely independent of the convulsive tonicities of the muscles, and due in no small measure to induration of the overlying soft parts, such hardening being the result of that loss of fluid which, as it affects the body in general, produces the rapid and extreme emaciation which is so characteristic of the disease.²

Though there is at times a prodromal period of restlessness and fretfulness, usually the disease is first indicated by an inability to nurse, the nipple being eagerly seized upon, but quickly dropped—an action that may be regarded as almost pathognomonic. Swallowing, difficult from the first, soon becomes impossible. The lower jaw in the earlier hours in many cases is dropped, but nearly always well-marked trismus is more or less quickly developed, at first intermittent, but later persistent. Opisthotonos in some degree is almost certain to be present, and in a large proportion of cases the tetanic convulsions become generalized, clonic exacerbations occurring as often as every half hour or hour, and capable of being induced at any time by pressure upon the abdomen (Morrison), or indeed by any external irritation, noise, touch, draft of air, etc.

All observers have noticed the peculiar cry, or rather whine, of the little patient. The bowels have in some cases been constipated, in others diarrhoea has been present. The temperature is generally decidedly elevated, and has been known to reach 111.2° F. Usually in from twelve to twenty-four or thirty-six hours collapse occurs, and the child speedily dies; though the fatal result may be deferred for a number of days or suddenly produced at any moment by spasm of the respiratory muscles.

Upon autopsy there has generally been found hyperæmia of the brain and cord with extravasations (commonly perithecal) in the spinal canal, occasionally in the meninges of the brain and in the ventricles. Very probably, as in true tetanus, these vascular conditions are the effect, and not the cause, of the spasms; and sometimes, doubtless, they are hypostatic.

As usually observed and commonly treated, the PROGNOSIS is very bad. Whether occurring in India or in Iceland, in the Rotunda Hospital in Dublin or in the Foundling Hospital in St. Petersburg, in the negro cabins of our Southern States or in New York or Washington, the subjects of it almost always die, generally in from six to forty-eight hours.³ It has been very exceptional to have 20 per cent.⁴ of recover-

¹ H. G. Lyttle of New York recently reported the case of a child two months old whose occipital bone was depressed and overlapped by the parietals, in which there had been no trismus, though the child had slight convulsive movements of the hands and rolling of the eyes.

² Parrot adds: "In the new-born in a state of health great difficulty is experienced in separating the jaws, the muscles that bring them together having, relatively, considerable power, and the infants making quite an active resistance when one attempts to separate them. It follows that when a pathological state exaggerates this tendency it may be thought that we have to do with a veritable trismus."

³ 80 per cent. of the cases collected by Hartigan (207-165).

⁴ 8 out of 40 cases tabulated by Smith; 8 out of 42 in the Stockholm Lying-in Hospital in 1834. It is very probable that these latter were cases of infantile meningitis.

ies, or even 15¹; and the non-fatal cases have almost invariably been those in which the disease appeared late and in mild form.

When treated by manipulation and position, as recommended by Marion Sims, the chances of recovery seem to be very much greater. Even in the acute cases under the care of Sims, of Wilhite, and of Hartigan, death occurred only in those seen late, after extravasations had taken place.

The Sims's method consists simply in releasing the overlapped occipital bone by manipulation (or, if that fails, by an operation), and then placing the child so that the head shall rest flat upon its side, the face looking directly toward the horizon. The success attending this postural treatment has been so remarkable that the practitioner cannot be justified in failing to determine the relative positions of the occipital and parietal bones and to keep the head resting upon its side.

Of the medicinal agents that have been administered (the same as those employed in ordinary tetanus), calabar and chloral have of late years been the favorites, chloral to-day standing highest in professional estimation. Calabar is best given hypodermically in doses of from $\frac{1}{12}$ to $\frac{1}{6}$ gr. of eserine; chloral, either by the mouth ($\frac{1}{2}$ to $1\frac{1}{2}$ or 2 grs.) or preferably by the rectum (2 to 4 grs.), either drug being pushed until relaxation takes place and sleep is secured, or toxic symptoms become so grave as to compel suspension of the treatment. Though favorable results have rarely followed such medication,² and (with but few exceptions) only in late-developed and mild cases that very possibly would have gotten well of themselves; yet as recovery from an acute attack has occasionally been reported, at least the chloral treatment should be instituted in every case not found to be promptly relieved by change of position of the head.

Whatever views may be entertained as to cause or nature, it is to measures that will prevent development that we must chiefly look for relief from this lockjaw of infants, that even in our own country annually carries off a great number of children—25,000, as estimated by Hartigan. If mechanically produced, its occurrence should be rendered impossible by having the child's head from the time of birth properly placed, and at regular intervals changed in position. If defective hygiene, personal and social, is the one common and constant condition wherever the disease prevails, then due regard should be had to dressing the umbilical (and perhaps the preputial) wound; to bathing, clothing, and keeping quiet³ the child; to thoroughly airing,⁴ warming, and disinfecting the lying-in room; and to overcoming, as far as may be possible, the evil influences of unfavorable atmospheric and climatic conditions.

¹ 5 out of 34 cases reported by Wallace from the Medical College Hospital of Calcutta.

² Monti, however, reported 11 recoveries out of 16 cases treated with calabar (68.75 per cent.), 3 out of 5 in his own practice; and Widerhofer was credited in 1871 with 6 recoveries in the 10 or 12 cases that he treated with chloral.

³ In these new-born children, though the reflex irritability is less than in those older, the response to irritation is very much greater, because of the lessened inhibitory power at this age (Soltmann).

⁴ By increasing the air-supply and lessening the number of beds the mortality at the Rotunda was in seven years reduced from about 1 in 7 to about 1 in 19 of the children born.

DISORDERS OF SPEECH.

By EDWARD P. DAVIS, A. M., M. D.

Development of Speech.

THE study of speech, a complex function, enlisting at once the activities of mind and body, invites the physician to enter alike the domains of the psychologist and physiologist.

Distinguishing man from beast, articulate expression has its foundation in purely mental phenomena; its successful accomplishment requires the reflex mechanism common to man and beast.

Let us consider as concisely as possible the physiology of speech.

DEVELOPMENT OF SPEECH IN THE INDIVIDUAL.—The earliest observation has noted in the common name of the new-born child its speechless condition; it is the infant, or not-speaking being. Born with a nervous system in a highly unstable condition, the babe is a most favorable recipient of the many impressions which stream upon it from all sides. With sight and hearing undeveloped, the field of early infantile impressions is limited to hunger, need of sleep, and cutaneous impressions. Speech under such conditions is inarticulate, an animal cry, unconscious and without intelligence. But with the growth of the cerebrum the child's environment suggests to the embryonic intelligence its primal impression. The parental relation is dimly apprehended, and designations of the father and mother are uttered in scarcely articulate sounds.

Sight and hearing open extensive fields of sensation, and with their development begin the primal, physical impressions from which proceed the emotions. The acoustic and optic centres of perception become established, and the mental formation of symbols and signs, an imitative process, marks the stage of childish cerebration, beyond which the savage often does not proceed. The symbolic function is the basis of language and of pictorial representation; as man requires the trade medium of the symbol for the interchange of his ideas, so his legal tender appears with the first emergence of mental enterprise. The hieroglyphic and the onomatopoeic word are as old as humanity.

The co-ordinating mechanism of speech is of equal development. With the growth of the child the varied impressions of education, of surroundings, of heredity, all are influencing speech. With mental growth, stimulated by these numerous impressions, comes the gradual mental habit of forming ideas after certain models—of trading, so to speak, in the coin of the country, of making and using a vocabulary. Intuition, induc-

tion, and deduction are established, the general nervous function of memory develops, observations are made, and mind and body, master and instrument, enter upon full activity.

PHYSIOLOGY OF NORMAL SPEECH IN THE ADULT.—Let us consider normal speech in the adult. From a purely mental aspect speech is not included in the nervous reflexes. The conception before the individual may arise without sight or sound, it may be the object of the mental processes only; but if it is to be communicated, or transferred from the subjective to the objective, it calls into play the denotative faculty or *facultas signatrix*.

As we are cognizant through the senses of phenomena only, so we communicate only phenomena, or more particularly symbols; the spoken or written word, the gesture, are necessary to make ideas tangible to another mind. The symbolic faculty, then, is the mental faculty most concerned in speech.

Cerebral localization has not included this faculty in its areas; it is assigned to the anterior cortex, which as yet is the indiscriminate site of the formation of ideas. The idea conceived, the symbol formed, the motor area whose integrity is essential, is found in the region commonly known as Broca's convolution, the posterior third of the left third frontal convolution. This region is especially connected with the corona radiata coming from the corpus striatum, with the corpus striatum and the anterior portion of the internal capsule: like the anterior, or motor, cornua of the spinal cord, it possesses giant, or branching, nerve-cells; its anatomy would assign to it a motor function. Its blood-supply is derived through the inferior frontal branch of the Sylvian vessel, whose occlusion in a case cited by Charcot was followed by complete aphasia.

Ferrier distinguishes just adjacent to this centre the motor centres for the tongue and mouth and upper extremities, showing an anatomical association of the processes of articulate and written speech.

But purely motor impulses comprise only a portion of the phenomena of speech. The external world must be brought into relation with the mind, and this is done through the perceptions. We may say that perceptions are apprehended sensations, and this apprehension demands a localized field of cerebral activity, as well as the motor energies. It seems natural enough that experiment should have located (Ferrier) perceptive, visual, and acoustic centres in the posterior cortical areas and temporo-sphenoidal lobes—that the motor and perceptive areas should be contiguous and sharing a common blood-supply.

The perceptive visual centre is found to occupy the occipital lobes, while the acoustic centre occupies the whole length of the first temporo-sphenoidal convolution.

As motor impulses found a path to the motor ganglia, and finally to the cord, so the course of sensory perceptive impressions can be traced back through the posterior internal capsule and through the optic thalami to the sensory columns of the medulla and cord.

Intuitive and sense perception, even when reinforced with motor power, cannot result in articulation. The mechanism of speech requires a co-ordinating centre, and this basal phonic centre of Kussmaul is located in the medulla near the origin of the hypoglossal and facial nerves. From the medulla proceed the nerves supplying the machinery of pho-

nation, the superior laryngeal nerve to the mucous membrane of the larynx and to the crico-thyroid muscle, the most important muscle of phonation. The remaining laryngeal muscles are supplied by the recurrent laryngeal; the motor processes of articulation are guided by the hypoglossal, facial, and fibres of the glosso-pharyngeal.

The larynx is a reed, with the addition of numerous resonance-cavities producing abundant overtones. It may be considered as a box composed of two segments, the lower of which has vertical motion upon the joint at the posterior junction of the superior and inferior segments. By this motion the tongue of the reed (vocal cords, stretching antero-posteriorly from lower segment to junction with upper segment) is tightened or relaxed, the vibratory blast of air coming through the trachea from the lungs. The superior aperture of the tube is guarded by the epiglottis and false vocal cords. As auxiliaries are the pharyngeal, oral, and nasal cavities, with the associated bony cavities of the skull, the soft palate acting as a movable partition or switch, the hard palate as a sounding-board or resonance-surface. The reed is applicable to the production of musical sounds; the tongue, lips, and teeth are required for the checks in those sounds, constituting the consonants or division utterances.

The curious phenomenon of the falsetto voice is thought by Helmholtz to be produced by the attenuation of the true cords and the vibration of their thinned edges.

DEVELOPMENT OF LANGUAGE.—The study of language demonstrates its origin to have been largely in exclamations and imitative sounds, from which our vowels can easily have arisen. The growth of all synthetic language illustrates the aggregation of accessory sounds about the primitive root-sound, while the common tendency to the insertion of consonants shows their addition to the primitive vowels. That the long vowels should have undergone countless modifications from the physical peculiarities and environment of those speaking them is but natural, for the number of vowels remaining in actual use in any language is not large. Consonants serve to make more clear by their separation of vowel-sounds the meaning to be conveyed; their development resulted from vowel changes, and their number is small.

The written characters of language represent only the usage of the majority. Individual speech and pronunciation vary as greatly as do languages themselves, and it is evident that the speech of any individual is as truly peculiar as his physical conformation.

To recapitulate, we find ideas, the material of speech, formed in the cerebral cortex. Speech-volition becomes motor impulse at Broca's convolution; such impulse passes along the internal capsule to the corpus striatum, where it is co-ordinated probably in the formation of syllables, thence to the medulla, whence the mechanism of the larynx receives its co-ordinated stimulation.

Disorders of Speech.

The classification of the disorders of speech should depend on the anatomical site of the lesions by which they are occasioned. Broadly

speaking, speech disorders resolve themselves into those of the formative apparatus for ideas and symbols and those of the purely co-ordinating and conducting mechanism. Abbreviating the schedule of Potter, we may say that the disorders of speech may be included in three classes—*alalia*, or lack of speech; *paralalia*, defective speech, the stammering of most observers; and *dyslalia*, difficult speech or stuttering.

The anatomy of the blood-supply of the speech-centres affords some explanation of *alalia*. The Sylvian artery will be remembered as the feeder of the speech-centres—an artery often the source of hemorrhage, as Charcot suggests, from the angle at which it leaves the carotid. Ducrot explains the frequency of left-sided softening and hemorrhage from the manner of origin of the left carotid, its axis being more nearly that of the ascending aorta and furnishing a ready channel for cardiac clots. In regard to the relative frequency of peripheral and central hemorrhage, Andral and Durand-Fardel cite 119 cases, of which but 17 were in the anterior or posterior lobes. It is admitted that cerebral lesions are largely those of the circulatory system, and the fact that such lesions result in the suspension of the activity of restricted areas is due to the circumstance that the cerebral arteries are terminal vessels giving off no anastomosing branches and supplying restricted areas only. With blood-supply so arranged it is not difficult to understand how the different portions of the motor centres may be separately involved, and thus the motor functions of speech may become singly at fault.

Inability to remember words and inability to form the motor impulses necessary for speech or writing are the common forms of *alalia* or *aphasia*, the former being known as *amnesic*, the latter as *ataxic alalia*. In addition, we may cite the failure of cerebral power occurring in general softening, in microcephalic brains, and the curious instances of voluntary silence from some strong belief or prejudice. Instances of the gradual resumption of cerebral function after its loss are not wanting; and, occurring where subsequent post-mortem examinations reveal a limited area of destruction of brain-tissue, they afford examples of the vicarious performance of cerebral functions by contiguous areas.

The phenomena of *amnesic alalia* are commonly seen in cases of recovery from cerebral hemorrhage, cerebral injury, and severe febrile affections. Numerous cases are recorded where the memory of things themselves remained, but the faculty of denoting them had been destroyed.

Kussmaul distinguishes here two conditions: 1st, where the word is entirely effaced from memory, 2d, where it still remains, but its association with that which it represents is suppressed. Cases of the second class are the most frequent, the fundamental part which the association of ideas plays in mental activity and the extent to which memory is dependent on association explaining this fact. A marked example of the failure of the denotative faculty lies in the cases of forgetfulness of one's own name, as described by Crichton in the case of an ambassador at the Russian court, who was obliged to say to his companion, when visitors asked his name, "For Heaven's sake, tell me what I call myself?" Piorry mentions the case of an aged priest who after right-sided paralysis lost entirely the use of substantives; wishing to ask for his hat, the word *hat* failed him utterly, and he was obliged to express himself in the remaining parts of speech: "Give me that which I place upon the

—;" but the word *head*, denoting the object most commonly in relation with the *hat*, was wanting also. When either hat or head was mentioned he spoke the word without difficulty.

Instances of failure in linguistic faculty are not uncommon. Witness a case, reported by Proust, of an Italian who after long residence in France, though understanding his native tongue, could speak only in French. Cases in which after acute disease one language is gone entirely while several others are retained are not wanting. A striking case of amnesic alalia was that of Lordat, a French physician, who thus described his malady: "I find myself deprived of the value of all words. If any words remain to me, they become useless, because I can no longer remember the manner in which I must co-ordinate them to express my thoughts. I am conscious that I recognize all ideas, but my memory does not suggest a word. In losing the memory of the meaning of spoken words I have lost that of their visible signs."

Fortunately, these cases are among the more tractable of cerebral disorders. Bristowe has reported a case wherein elementary instruction in speech-formation was tried with marked success. The patient, aged thirty-six, after a violent cerebral disturbance without traumatism became paraplegic, speechless, and deaf. Gradual recovery ensued until, seven months after his first illness, he was admitted into St. Thomas's Hospital in the following condition: Numbness and paresis in left leg, less in left arm; special senses healthy; no incontinence; some pain about head and neck; complete loss of speech. It was found that the patient was very intelligent, wrote legibly, could make all kinds of voluntary movements with lips, tongue, and teeth, and was capable of vocal intonation; articulation alone was lacking.

The law of the evolution of language designates as primitive forms of word-signs those words affirming qualities, while those denoting relative positions are of secondary formation (Whitney.) Remembering, also, the fact that amnesia in general "is a regression from the new to the old, from the complex to the simple, from the voluntary to the automatic, from the least organized to the best organized,"¹ we are able to understand the cause of amnesic alalia, and also the steps of the process of recovery, in which the inverse order is observed.

Amnesic alalia can hardly be regarded as susceptible of treatment other than as a general neurasthenia. Though we may develop memory by cultivating the association of ideas and by repetition, yet, regarding it as a general function of the nervous system, it is evident that recovery from its disorders is conditioned by the general vigor of the nervous centres. A partial recovery usually occurs in such cases; complete recovery is more infrequent.

Ataxic alalia, the failure of the motor powers of speech, occurs in all forms of general paralysis, most typically in bulbar paralysis. This disease is fully described in the standard works on neurology. Ataxic alalia will also occur in disseminated sclerosis, posterior spinal sclerosis, dementia paralytica, and cretinism. It forms in general disorders an instructive symptom, and is to be distinguished by a tremulous utterance and by facial spasm from the hesitation of the stammerer and from the convulsive utterance of the stutterer.

¹ Ribot, *Diseases of Memory*.

Paralalia embraces all abnormalities of speech, from trivial mannerisms to difficulties in the utterance of certain letters, including those painful defects which depend upon physical malformations.

The free discussion of paralalia would cover the domain of elocution; the physician is called upon to advise in those cases only where either a physical malformation is evident or the difficulty experienced by the patient in enunciating certain letters has led to a suspicion of the existence of malformation. The former cases lie in the province of the surgeon; the latter come within the scope of those elocutionists, speech-trainers, and instructors who hope to cure stammering and stuttering.

Discrimination between stammering and stuttering will give the physician a basis for judgment from which he can reasonably offer encouragement in many cases and avoid the creation of false hopes in others. As a cardinal point of difference, it will be remarked that in the case of the stutterer the muscles of phonation are thrown into a state of spasm when speech is attempted, while in the stammerer their movements are merely lacking in proper co-ordination. It may also be observed that the respiration of the stammerer is marked by irregular contractions of the diaphragm, which render the expiratory blast of air irregular in its delivery. In the stutterer the spasm is pronouncedly laryngeal and facial. The nervous embarrassment of the stutterer is proverbial, and is increased by excitement, while a moderate degree of excitement, stimulating respiration, greatly improves the speech of the stammerer.

Whispering, a difficult respiratory act, exaggerates the stammerer's fault, but the spasm of the stutterer is often relaxed by the diminished pressure of whispered breath.

As articulation is effected by the larynx and the oral organs, the stutterer makes his spasmodic articulation particularly noticeable, while the stammerer finds little difficulty in the utterance of words. *R*, *L*, *S*, and other letters whose enunciation demands the continued expiratory blast, are imperfectly uttered by the stammerer, while these letters when joined to a long vowel-sound occasion little or no difficulty for the stutterer.

TREATMENT.—It follows that if stammering is recognized as inco-ordinate enunciation, owing largely to irregular action of the diaphragm, any training of the respiratory muscles which will ensure a regular delivery of the expiratory air will improve this defect. It follows, then, that the treatment of stammering resolves itself into careful attention to general hygiene, associated with such persistent respiratory and vocal gymnastics as shall effectually develop regularity, depth, and co-ordination of action on the part of all the muscles concerned in the act of respiration. Drugs will be of service only as aids to the correction of errors in the essential physiological functions. In the child the powers of imitation may be enlisted to effect a cure, and the familiar fact that the habits of childhood are easily formed would indicate this as the best time for treatment.

Childhood once passed, however, the steadiness of purpose of the adult is requisite to break up a confirmed habit, and active treatment should be deferred until after adolescence. Most important in all cases are judicious moral influences exerted by those about the patient, the ridicule so often visited upon the unfortunate stammerer being most harmful in its consequences. The many tricks and devices so often employed in these

cases are of use simply by varying the monotony of vocal drill; they may be employed or abandoned as the judgment of the physician may dictate.

Regarding the prognosis in these cases, it follows that with a fairly developed and healthful nervous system, reinforced by proper mental and physical hygiene, the stammerer's case is far from hopeless in the hands of a patient and intelligent physician.

An unfavorable prognosis would be demanded by hereditary defects and vices of the nervous system, by the lack of general nervous vitality, by enfeeblement of the will and the mental tone of the individual, by advanced age, and by irremediable hygienic conditions. Under favorable conditions recovery should be the rule.

DYSLALIA, OR STUTTERING.—Recalling to mind the points of difference between stuttering and stammering, it becomes evident that while the prospect of success in the treatment of the stammerer is often favorable, the case of the stutterer presents such difficulties as render it too frequently hopeless.

We may liken the confirmed stutterer to those rare cases of chorea which defy treatment, and to those cases of hereditary deterioration of the nervous system where the most patient and painstaking care fails to overcome the defect. The laryngeal and facial spasms depend upon no malformation for their exciting cause; hence surgery fails to remedy the defect. Drugs which are given with hope of invigorating the nervous system have only a general tonic influence, while the motor depressants and antispasmodics find but partial success. We must again rely upon hygiene, and also upon those aids to enunciation which come from rhythmical associated movements, such as stamping with the foot, beating time with the hand, the employment of a sing-song tone, or other modes of specially rhythmic enunciation. The sing-song mode of utterance is a familiar resource with parents in attempting to aid a stuttering child, and the measured forms of articulation offer the only vocal drill that possesses any permanent value. It is especially essential in the stutterer's case that the patient be protected from ridicule and from all disturbing emotions: the burden of difficult speech is sufficient to greatly depress the nervous system without the added suffering of emotional distress. It is evident that childhood, characterized as it is by especial instability of the nervous system, is the period when we can hope for the best results from care and training; the long-formed habits of the adult are rarely broken.

We have thus traced the disorders of speech to their origin as symptoms of grave central lesions of the nervous system, as results of heredity or of a general neurasthenic condition; very rarely are they dependent upon malformations of the organs of speech.

The treatment of such malformations, when they occur, is largely unsatisfactory and is seldom curative.

The thorough treatment of those speech disorders that are not susceptible of surgical aid would embrace such mental and physical hygiene and training as should ensure the formation of a thoroughly conceived vocabulary and its co-ordinated expression by words either spoken or written. The study of expression in its highest forms would necessarily conduct the investigator far into the realm of the plastic, harmonic, and literary arts.

ALCOHOLISM.

By JAMES C. WILSON, M.D.

DEFINITION.—Alcoholism is the term used to designate collectively the morbid phenomena caused by the abuse of alcohol.

SYNONYMS.—Alcoholismus, Ebrietas, Ebriositas, Temulentia, Drunkenness, Delirium potatorium, Mania potatorium, Delirium tremens, Chronic alcoholic intoxication, Dipsomania; *Ger.* Trunkenheit, Trunksucht; *Fr.* Ivresse, Ivrognerie.

These terms are in common use to describe such conditions and outbreaks in alcoholic individuals as amount to veritable morbid states or attacks of sickness, but they are not interchangeable, nor are they all sufficiently comprehensive to constitute true synonyms. They are names applied to various conditions due to acute or chronic alcohol-poisoning properly and distinctively comprehended under the general term alcoholism.

CLASSIFICATION.—It was formerly the custom to restrict this term to affections of the general nervous system induced by continued excesses in the use of alcoholic drinks.¹ But the nervous system bears the brunt of the attack and suffers beyond all others alike in transient and in continued excesses. The artificial restriction of the term to the cases caused by continued excesses was therefore illogical in itself, and has been productive of much needless difficulty in the treatment of the subject and in the classification of the cases. The use of the term chronic alcoholism to denote an established condition, and of acute alcoholism to describe outbreaks of various kinds which occur in individuals subject to that condition, has also proved a source of embarrassment to the student. Not less vague has been the employment of such terms as delirium tremens, mania-a-potu, and the like, which are unsatisfactory in themselves, and tend to exalt symptoms at the expense of the morbid condition of which they are only in part the manifestation. I am of the opinion—which is at variance with established usage—that the systematic discussion of alcoholism requires that all forms of sickness, including drunkenness, due to that poison must receive due consideration, and that the term acute alcoholism, hitherto used in a sense at once too comprehensive and too variable, should be reserved for those cases in which the sudden energetic action of the poison is the occasion of like sudden and intense manifestations of its effects. Furthermore, the uncertainty and lack of precision in the use of the terms acute and chronic alcoholism are due to errors of theory formerly almost universal in medical

¹ Anstie, *Reynolds's System of Medicine*, vol. ii., 1868.

writings and popular belief concerning the disease. The chief source of these errors was the recognition only of the more acute nervous affections caused by alcoholic excess—delirium tremens, maniacal excitement, and terrifying hallucinations—and the belief that these conditions occurred only after a temporary abstinence in the course of habitual or prolonged indulgence. It has now long been known that abstinence from drink by no means necessarily precedes the outbreak of mania or delirium, and modern researches have established the existence of a chronic alcoholic intoxication of long duration extending over a period of months or years, in which such outbreaks merely exhibit the full development of symptoms that have already been occasionally and partially recognizable.

The following arrangement of the topics will facilitate the discussion of the subject in the present article, and serve, I trust, a useful purpose for the classification of cases in accordance with existing knowledge:¹

I. Acute Alcoholism: Drunkenness, Debauch.

A. Ordinary or Typical Form.

B. Irregular Forms.

1. Maniacal;

2. Convulsive;

3. In persons of unsound mind.

C. Acute Poisoning by Alcohol: Lethal doses.

II. Chronic Alcoholism.

A. Visceral Derangements.

1. Local disorders:

a. Of the digestive system;

b. Of the liver;

c. Of the respiratory system;

d. Of the circulatory system;

e. Genito-urinary system.

2. Disorders of special structures:

a. Of the locomotor apparatus;

b. Of the skin.

3. General disorders:

a. The blood;

b. Obesity;

c. Cachexia.

B. Derangements of the Nervous System: Cerebro-spinal Disorders.

1. Cerebral disorders.

2. Spinal disorders.

3. Disorders of the peripheral nerves.

4. Disorders of the special senses.

C. Psychical Derangements.

1. The moral sense.

2. The will.

3. The intellect.

4. Alcoholic delirium in general.

5. Delirium tremens.

6. Alcoholic insanity:

a. Melancholia;

b. Mania;

c. Chronic delirium;

d. Dementia;

e. Paretic dementia.

III. Hereditary Alcoholism.

IV. Dipsomania.

HISTORY.—The history of the abuse of alcohol would be the history of society from the most remote period until the present time, not only among civilized but among barbarous races of men, for the abuse of narcotics, of which alcohol is at once the most important and the most widely used, forms a dark background to the broad picture of healthful human progress. In truth, the most sketchy account of our knowledge of the effects of alcoholic excess, as manifested in the individual and in society at large, interesting as it might prove to the general reader, would be out of place in this article. To be of real

¹ This classification is in part based upon that of Lentz, *De l'Alcoholism et de ses Diverses manifestations, etc.*, Bruxelles, 1884—a prize essay.

value it would necessarily embody a record of experiences so vague, facts so indeterminate, opinions so at variance, and citations so numerous, that they would require for their mere presentation a volume rather than an article. The object of the writer in the following pages shall be, therefore, to present the subject in its present aspect, without reference, beyond that which is absolutely necessary, to considerations of mere historical interest. This being the case, he considers further apology for the lack of laborious historical studies unnecessary.

ETIOLOGY.—*A. Predisposing Influences.*—We are at this point confronted with a series of problems the complex nature and grave importance of which appeal with peculiar urgency to all thoughtful physicians. Their discussion, however, involving as it does unsettled questions of great moment in social science, is beyond the scope of the present article. A few practical points only can occupy our attention.

The influences which predispose to alcoholism arise from unfavorable moral, social, and personal conditions.

Among the unfavorable moral conditions may be mentioned a want of wholesome public sentiment on the subject in communities. This arises too often, but by no means exclusively, from poverty and its attendant evils ignorance and vice. Rum is at once the refuge and the snare of want, destitution, and sorrow. To the vacant and untrained mind it brings boons not otherwise to be had—excitement and oblivion. That both are brief and bought at a ruinous cost exerts little restraining influence. Of equal if not greater importance are the influences which spring from ill-regulated and demoralizing domestic relations, and the absence of motive and the contentment which properly belong to the family as an organization. Everywhere also do we find in example a potent influence. In the individual, in addition to hereditary propensities, the evil results of a lax, over-indulgent, or vicious early training, as shown in a want of power of application, of moral rectitude, in self-indulgence, craving for excitement, and a weak will, powerfully predispose to the temptations of alcoholic excess.

Among social conditions which must be regarded as predisposing influences occupation takes the first rank. The occupations which render those pursuing them especially liable to alcoholism may be divided into two classes—those in which the temptation to drink is constantly present, and those in which the character of the work begets a desire for stimulation, while the opportunities for the gratification of the desire are but little restricted.

To the first of these groups belong all classes of workmen in distilleries, breweries, and bottling establishments; keepers and clerks of hotels, public houses, and restaurants; the barmen and waiters in the same trades; the salesmen who travel for dealers in wines and spirits. To this group must also be referred the professional politician of the lowest order. These occupations have furnished by far the larger number of cases that have come under my care, both in hospital and in private practice.

To the second class belong occupations involving great exposure to the inclemency of the weather. We frequently find cabmen, expressmen, coal-heavers, hucksters, and street-laborers habitually addicted to excesses in alcohol. The stringent regulations of corporations exert a powerful

protective influence in the case of men employed on railways, ferry- and other steamboat service, and in and about dépôts and stations. Exhausting toil under unfavorable circumstances as regards heat and confinement predisposes to drink, as in the case of foundrymen, workers in rolling-mills, stokers, and the like. The men-cooks who work in hotels and restaurants are especially liable to alcoholism. Monotony of occupation, as in the cases of cobblers, tailors, bakers, printers, etc., especially when associated with close, ill-ventilated workrooms and long hours of toil, exerts a strong predisposing influence. Persons following sedentary occupations suffer from excesses sooner than those whose active outdoor life favors elimination. To the monotony of their occupations may be ascribed in part, at least, the disposition of soldiers, ranchmen, sailors, etc. to occasional excesses as opportunities occur. Irregularity of work, especially when much small money is handled, as happens with butchers, marketmen, and hucksters, also often leads to intemperance.

The lack of occupation exerts a baleful influence. Men-about-town, the frequenters of clubs, dawdlers, and quidnunes often fall victims to a fate from which occupation and the necessity to work would have saved them. In this connection it may be permitted to call attention to the custom of treating as enormously augmenting the dangers to which such persons are habitually exposed in the matter of alcoholic excesses. The occasional moderate use of alcohol in the form of wine with food and as a source of social pleasure is not fraught with the moral or physical evils attributed to it by many earnest and sincere persons. It is, on the contrary, probable that the well-regulated and temperate use of sound wines under proper circumstances and with food is, in a majority of individuals, attended with benefit. Those who suffer from the effects of excesses do not usually reach them by this route, nor would they be saved by any amount of abstinence on the part of temperate and reasonable members of society.

When we turn our attention to the unfavorable personal conditions which predispose to alcoholism, we at once enter upon the familiar field of work of the practical physician. Numerous influences having their origin in the individual himself, some occasional, others constant, all urgent, demand our careful consideration. Some of the conditions out of which these predisposing influences spring are tangible and easy of recognition; others are elusive and uncertain. To point them out is, unfortunately, not to remedy them. As a rule, they have wrought their evil effects long before the individual has cause to regard himself in the light of a patient.

First in importance is heredity. A peculiar inherited constitution of the nervous system is as influential in leading to alcoholic excess and in aggravating its disastrous effects as any other cause whatsoever. A considerable proportion of individuals who suffer from alcoholism are found upon inquiry to come of parents who have been addicted to drink. A still greater number belong to families in which nervous disorders, and in particular neuralgia, epilepsy, and insanity, have prevailed. Others, again, are the offspring of criminals. It can no longer be doubted that particular causes of nervous degeneration in one or both parents may lead to the hereditary transmission of a feeble nervous organization, which, on the one hand, renders its possessor peculiarly liable to neuroses

of every kind, and, on the other hand, an easy prey to the temptation to seek refuge from mental and physical suffering in occasional or habitual narcotic indulgence. Thus, as Anstie pointed out, "the nervous enfeeblement produced in an ancestor by great excesses in drink is reproduced in his various descendants, with the effect of producing insanity in one, epilepsy in another, neuralgia in a third, alcoholic excesses in a fourth, and so on." When it is possible to obtain fairly complete family histories, covering two or three generations, in grave nervous cases, facts of this kind are elicited with surprising frequency. The part which heredity plays in many of the more inveterate and hopeless cases of alcoholism is wholly out of proportion to the obvious and easily recognizable part played by momentary temptation. To the failure to recognize the real agency at work in such cases must be ascribed the disappointment of too many sanguine and unsuccessful social reformers.

Various forms of disease exert a predisposing influence to alcoholic excesses. In the first place, bodily weakness and inability to cope with the daily tasks imposed by necessity impel great numbers of persons of feeble constitution, especially among the laboring classes, to the abuse of alcohol.

In the second place, many conditions of chronic disease attended by suffering are susceptible of great temporary relief from the taking of alcohol. Especially is this the case in the neuralgias, in phthisis, in dysmenorrhœa and other sexual disorders of women, in the faintness and depression of too-prolonged lactation, in the pains and anxieties of syphilis, and in the malaise of chronic malaria. When the patient has learned that alcohol is capable of affording relief from suffering, it is but a short step through ignorance or recklessness to habitual excess.

The administration of alcohol during convalescence from attacks of illness is not unattended by the danger of subsequent abuse. It is well for the physician to inform himself of the hereditary tendencies and previous habits of the patient before assuming the responsibility of continuing alcohol beyond the period of acute illness under these circumstances; and it is a rule never to be disregarded that the stimulant ordered by the physician is to be regulated by him in amount, and discontinued when the patient passes out of his care.

Irregularities of the sexual functions in both sexes, and especially sexual excesses, strongly predispose to alcoholism. The custom of administering to young women suffering from painful menstruation warming draughts containing gin, brandy, or other alcoholic preparations in excessive amounts is a fertile cause of secret tippling.

The abuse of tobacco, to the depressing effects of which alcohol is a prompt and efficient antidote, must be ranked as an important predisposing influence.

Depressing mental influences of all kinds tend strongly to drinking habits. This is true of persons in all classes of society.

Habit constitutes an influence the importance of which can scarcely be over-estimated. Much of the drinking done by active business-men has no other cause than this. Alcohol, like opium and other narcotics, exerts its most pernicious influence through the periodical craving on the part of the nervous system for the renewal of the stimulating effects which it causes, while it progressively shortens the period and diminishes the

effect by its deteriorating action upon the nutrition of the peripheral and central nervous tissues.

B. The Exciting Cause.—Alcohol, or ethyl hydrate, is the product of the fermentation of solutions which contain glucose or a substance capable of transformation into glucose. Other alcohols, as propyl, butyl, and amyl alcohol, etc., are also formed in small quantity in the fermentation of saccharine liquids. Ethyl alcohol is the type of the series, and forms the normal spirituous ingredient of ordinary alcoholic beverages. The others when present, except in minute quantities, constitute impurities. Their toxic effects are much more pronounced than those of ethyl alcohol.

Alcohol is a colorless mobile liquid having an agreeable spirituous odor and a pungent, caustic taste, becoming fainter upon dilution. It mixes with water and ether in all proportions.

Alcoholic beverages form three principal groups: 1, spirits, or distilled liquors; 2, wines, or fermented liquors; and 3, malt liquors.

1. The various spirituous liquors, as whiskey, gin, rum, brandy, etc., contain, in addition to the ethyl alcohol and water common to them all, varying minute proportions of ethereal and oily substances to which each owes its peculiar taste and odor. These substances are cœnanthic, acetic, and valerianic ethers, products of the reaction between the corresponding acids and alcohol, and various essential oils. Traces of the other alcohols are also present. Amyl alcohol, the so-called fusel oil, is present in new and coarse spirit, but especially in that derived from potatoes, in considerable amounts. It is to this ingredient that potato spirit owes its peculiarly deleterious properties. Richardson¹ experimentally produced with amyl alcohol phenomena analogous to delirium tremens in man. Spirits also frequently contain sugar, caramel, and coloring matters derived from the cask, to which certain products of the still also owe in part their flavor. These liquors are of varying strength, and contain from 45 to 70 per cent. of absolute alcohol by volume.²

Liqueurs (anise, kümmel, curaçoa, Benedictine, etc.) are the products of the distillation of alcohol with various aromatic herbs, sweetened, or of its admixture with ethereal oils and sugar. These compounds contain a very high percentage of alcohol. Two of them, absinthe and kirsch, by reason of their peculiarly dangerous properties deserve especial mention.

Absinthe is an alcoholic distillate of anise, coriander, etc. with the leaves and flowers of the *Artemisia absinthium*, which yields a greenish essence. This liqueur contains from 60 to 72 per cent. of alcohol, and exerts a specific pernicious effect upon the nervous system, largely due to the aromatic principles which it contains.³ Kirsch, which owes its pecu-

¹ *On Alcohol*, Lond., 1875.

² Vide Baer, *Der Alcoholismus*, Berlin, 1878.

³ As early as 1851, Champouillon (referred to by Husemann, *Handbuch der Toxicologie*) called attention to the fact that the French soldiers in Algiers, in consequence of excessive indulgence in absinthe, suffered especially from mania and meningitis. Decaisne (*La Temperance*, 1873, *Étude médicale sur les buveurs d'absinthe*) found absinthe in equal doses and of the same alcohol concentration to act much more powerfully than ordinary spirits, intoxication being more rapidly induced and the phenomena of chronic alcoholism earlier established. Pupier (*Gazette hebdom.*, 1872) found in those addicted to the use of absinthe marked tendency to emaciation and to cirrhosis of the liver; and Magnan (*Archives de Physiol.*, 1872) asserts that the chronic alcoholism due to this agent is characterized by the frequency and severity of the epileptic seizures which accompany it. There is reason to believe that the consumption of absinthe in the cities of the United States is increasing.

liar flavor to the oil of bitter almonds and hydrocyanic acid which it contains in varying and often relatively large proportions, is still more dangerous. The toxic effects produced by these liqueurs are of a very complex kind, and scarcely fall within the scope of this article.

2. Wines are the product of the fermentation of the juice of the grape. Their chemical composition is extremely complex. They owe their general characteristics to constituents developed during fermentation, but their special peculiarities are due to the quality of the grape from which they are produced, the soil and climate in which it is grown, and the method of treatment at the various stages of the wine-making process. So sensitive are the influences that affect the quality of wine that, as is well known, the products of neighboring vineyards in the same region, and of different vintages from the same ground in successive years, very often show wide differences of flavor, delicacy, and strength.

The most important constituent of wine is alcohol. To this agent it owes its stimulating and agreeable effects in small, its narcotic effects in large, amounts. The proportion of alcohol, according to Parkes, Bowditch, Payen, and other investigators, varies from 5 to 20 per cent. by volume, and in some wines even exceeds the latter amount. The process of fermentation, however, yields, at the most, not more than 15 to 17 per cent. of alcohol, and wines that contain any excess of this proportion have been artificially fortified.

Further constituents of wine are sugar, present in widely varying amounts, and always as a mixture of glucose and levulose—inverted sugar; traces of gummy matter, vegetable albumen, coloring matters, free tartaric and malic acid, and various tartrates, chiefly potassium acid tartrate, or cream of tartar. In some wines there are found also traces of fatty matters. Tannin is likewise found. Small quantities of aldehyde and acetic acid are due to the oxidation of alcohol. The acetic acid thus formed further reacts upon the alcohol, forming acetic ether. To the presence of traces of compound ethers, acetic, cœnanthic, etc., wines owe their bouquet. Carbon dioxide, produced in the process of fermentation, is retained to some extent in all wines, and is artificially developed in large quantities in champagnes and other sparkling wines.

Much of the stuff sold as wine, even at high prices, in all parts of the world, is simply an artificial admixture of alcohol, sugar, ethereal essences, and water. The wines rich in alcohol are especially liable to imitation.

Wine is the least harmful of alcoholic drinks. In moderate amounts and at proper times its influence upon the organism is favorable. In addition to its transient stimulating properties, it exerts a salutary and lasting influence upon the nutrition of the body. Only after prolonged and extreme abuse, such as is sometimes seen in wine-growing countries, does it lead to alcoholism.

3. Malt liquors—beer, ale, porter, stout, etc.—are fermented beverages made from a wort of germinated barley, and usually rendered slightly aromatic by hops. This process is known as brewing. Malt liquors, of which beer may be taken as the type, contain from 3.75 to 8 per cent. by volume of alcohol, free carbon dioxide, variable quantities of saccharine matters, dextrin, nitrogenized matters, extractive, bitter and coloring matters, essential oil, and various salts. Much importance has

been ascribed to the quantity of malt extractive in beer: it has even been seriously spoken of as fluid bread. But, granting the nutritive value of the malt extractives, it is, as compared with the nutritive value of the grain from which they are derived, so small that beer must be regarded as a food of the most expensive kind.

Sound beer is wholesome and nutritious, and serves a useful purpose in the every-day life of a considerable part of the earth's population. But it is wholesome only in moderate amounts. Its excessive consumption results in progressive deterioration of mind and body. Undue accumulation of fat, diminished excretion of urea and carbon dioxide, are followed by disturbances of nutrition. Incomplete oxidation of the products of tissue-waste leads to the abnormal formation of oxalates, urates, etc., to gout, derangements of the liver, and gall-stones. In long-continued excesses in beer one of the effects of the lupulin is to enfeeble the powers of the reproductive organs. The inordinate consumption of beer induces intellectual dulness and bodily inactivity, and lessens the powers of resistance to disease. The dangers of acute and chronic alcoholism are obvious. Five glasses of beer of 5 per cent. alcohol strength contain as much alcohol as half a beer-glassful of spirits of 50 per cent.

The moderate consumption of beer in communities is to some extent a safeguard against alcoholism. To secure this end, however, the beer must be sound and of light quality. The stronger beers, and especially those which are fortified with coarse spirits, besides the direct dangers attending their use, tend rapidly to the formation of spirit-drinking habits.

The action of alcohol varies according to its degree of concentration, the quantity ingested, and its occasional or habitual use. On the one hand, when well diluted, taken in small amount and occasionally only, it may be without permanent effect upon any function or structure of the body; on the other hand, its frequent administration in large doses and but little diluted is, sooner or later, surely followed by widespread tissue-changes of the most serious kind.

The Physiological Action of Alcohol.—Alcohol is very rapidly taken up by absorbent surfaces. According to Doziel,¹ it has been detected in the venous and arterial blood and in the lymph of the thoracic duct a minute and a half after its ingestion. It is very slightly if at all absorbed by the unbroken skin. Denuded surfaces and extensive wounds permit its absorption, as in the case of surgical dressings, and instances of intoxication from this cause have been recorded. It is also freely absorbed in the form of vapor by the pulmonary mucous surfaces. Some surfaces, as the pleura and peritoneum, absorb it, as has been demonstrated by the effects following its injection into those cavities. Its constitutional effects are also rapidly developed after hypodermic injection. Under ordinary circumstances, however, it is by the way of the absorbents and veins of the gastric mucous membrane that alcohol finds its way into the blood. It is probable that the greater part of the alcohol taken into the stomach undergoes absorption from that organ, and that very little of it reaches the upper bowel. Alcohol is readily absorbed by the rectal mucous membrane. Having entered the blood,

¹ *Pflüger's Archiv für Physiologie*, Band viii., 1874.

it reaches all the organs of the body, and has been recovered by distillation not only from the blood itself, but also from the brain, lungs, liver, spleen, kidneys, and various secretions.¹

Lentz and other observers believe that certain organs have a special affinity for alcohol. The author named and Schulinus place the brain first in this respect, and in the next rank the muscles, lungs, and kidneys. But Lallemand and Perrin regard the liver and the brain as having an equal affinity for alcohol. The opinion of Baer, who rejects the view that alcohol has an especial predilection for particular organs, is more in accordance with known physiological law. This observer holds that alcohol, having found its way into the blood, circulates uniformly throughout the whole organism, and explains the greater amount recoverable from certain organs as due to the fact that these organs contain more blood than others.

The elimination of alcohol is at first rapid, afterward very gradual. It begins shortly after ingestion, and in the course of two or three hours one quarter, and perhaps much more, of the amount passes from the organism. Nevertheless, after the ingestion of large amounts traces of alcohol were discovered on the fifth day in the urine by Parkes and Wollowicz, although the elimination by the lungs had entirely ceased.

Elimination takes place for the most part by way of the kidneys, the lungs, and the skin; alcohol has been recovered also from the bile, saliva, and the milk.

Whatever may be the affinity of certain organs for alcohol, whatever the channels by which it is eliminated, the general belief is that some portion of it undergoes chemical decomposition within the body. The steps of this process and its ultimate results are as yet unknown; nor, indeed, are the proportional amounts decomposed and eliminated established. Some observers regard the amount eliminated as less than that decomposed. Others suppose that the amount consumed within the body is relatively very small as compared with that disposed of by elimination. It is, however, established that the sojourn of alcohol in the body, unlike that of many other toxic substances, is transient, and that in the course of from twenty-four to forty-eight hours after the ingestion of a moderate amount there remain only traces of this substance.

The local action of alcohol upon organic tissues depends upon its volatility, its avidity for water, its power to precipitate albuminous substances from solution and to dissolve fats, and, finally, upon its antiseptic properties.

Applied externally and permitted to evaporate, it produces a fall of temperature and the sensation of cold; if evaporation be prevented, a sensation of warmth is experienced, the skin reddens, and, if the action be prolonged, desquamation results. The sensation produced when diluted alcohol is applied to mucous surfaces is burning and stinging; when concentrated, it may excite inflammation.

Dilute alcohol has been much employed as a surgical dressing for wounds and ulcerated surfaces. Its value for this purpose depends on its stimulating properties, by virtue of which it exerts a favorable influence upon granulating surfaces; and on its antiseptic qualities, which are, however, much inferior to those of salicylic and carbolic acids among organic substances and to the chlorides among the inorganic salts.

¹ Strauch, *De demonstratione Spiritus Vini in corpus ingesti*, Dorpati, 1862.

The direct action of alcohol upon the mucosa of the digestive system depends upon the quantity ingested and degree of concentration. In moderate amounts and diluted to the extent of 50 per cent. or more, it produces a sensation of warmth in the tissues over which it passes. This sensation is due in part to the impression upon the nerve-endings, and in part to reflex hyperæmia, which is at once excited. In individuals unaccustomed to its use reflex contractions of the constrictor muscles of the pharynx, with gagging, are sometimes provoked. The secretion of saliva and of the gastric juice is increased, diluted alcohol being, in respect to its physiological effect in stimulating the buccal and gastric mucous glands, inferior to no other agent. This action is due as much to reflex as to local action, as has been shown experimentally by the application of a few drops of alcohol to the tongue of a dog with gastric fistula, increased secretion of gastric juice immediately resulting.

It is in consequence of this action that moderate doses of diluted alcohol exert a favorable influence upon the appetite and digestion. Increased amounts of food are well borne; fats especially are more tolerable and better digested; and a more energetic peristalsis favors the absorption of the food solutions. In those habituated to the use of alcohol these effects do not always follow; and if the amount be increased or the repetition become frequent, some part of the alcohol undergoes in the stomach, with the food, acid fermentation, and acid eructations or vomitings occur. With these phenomena is associated gastro-hepatic catarrh with its characteristic symptoms—loss of appetite, feeble digestion, diarrhoea alternating with constipation, sallowness, mental depression, and headache. In still greater amounts and little diluted, alcohol is capable of exciting acute gastritis or congestion and catarrhal inflammation of the liver.

When we come to study the action of alcohol upon the circulatory system, we find that in small doses it has little or no influence either upon the action of the heart or the condition of the vessels. In augmented amounts it increases the action of the heart both in force and frequency, and the arterial blood-pressure. After large doses these effects quickly pass away, and the circulation becomes depressed. The heart's action grows feebler, often slower, the pulse weaker; blood-pressure sinks and arterial tension is diminished. Its physiological action is that of a direct stimulant to the heart and the pneumogastric nerve; its toxic action, that of a depressant. Upon the vaso-motor system the action is from the first that of a depressant. Dilatation of capillary vessels and increased afflux of blood manifest themselves in the flushed face, brilliant eyes, and warmth of surface which are familiar phenomena. Frequent repetition tends to permanently impair the activity of the peripheral circulation. Hence the visible vascular twigs and rubicund nose that characterize the physiognomy of the habitual drinker.

This congestion no less affects the internal organs, setting up, by interference with their functions, chronic derangements of nutritive processes on the one hand, and on the other the liability to acute local diseases and complications.

The reactions which take place between the blood and alcohol remain, notwithstanding the energy devoted to their investigation, among the unsolved problems of physiological chemistry. It were a profitless task to here review the researches into this subject or to set forth their conflict-

ing results. It may be stated that conclusions based upon the reactions between blood drawn from the vessels and tested with alcohol in the laboratory are wholly inapplicable to the inquiry. While it is generally conceded that some part of the alcohol ingested undergoes decomposition within the organism, what the steps of the process are and what the products are have not yet been demonstrated. Rossbach and Nothnagel¹ state that it has not yet been possible to detect in the organism the products of the oxidation of alcohol—namely, aldehyde, acetic acid, and oxalic acid; nevertheless, acetic acid formed in the economy by the general combustion of alcohol may form acetates, which, undergoing decomposition, are transformed into carbonates and water, and are eliminated as such in the urine.² This view is also held by Parkes.³

According to Peeters, the action of alcohol upon the blood may be summed up as follows: That portion of the ingested alcohol which undergoes decomposition takes from the blood some part of its oxygen for this purpose, with the result of a diminished amount of oxygen and an increase of carbon dioxide, the blood thus being made to resemble venous blood. A part of the oxygen destined for the oxidation of waste products being thus diverted, these substances are not completely transformed. In this respect also blood charged with alcohol resembles venous blood. Alcohol even when diluted is capable of retarding the combustion of oxidizable organic substances, and there is no reason to doubt that this agent has in the blood the same chemical properties that it elsewhere possesses.

The exhalation of some part of the alcohol circulating in the blood by the way of the pulmonary mucous membrane interferes with the elimination of carbon dioxide, with the result that the latter agent further tends to accumulate in the blood.⁴

Alcohol must act, to some degree at least, directly upon the water of the blood and upon its albuminoid principles. The products of the reactions normally taking place within the corpuscles pass with greater difficulty into serum containing alcohol as the current of osmosis tends rather from the serum to the corpuscles. It is in accord with this fact that the corpuscles of alcoholized animals have been found relatively large.

The blood of individuals who have died in a state of alcoholic intoxication has been frequently found to contain an unusual amount of fatty matter in a fine state of subdivision.

Upon the respiration the influence of alcohol is twofold: it modifies the respiratory movements and the results of the respiratory processes. After moderate doses the movements are accelerated without disturbances of rhythm; after large doses the respiratory acts become embarrassed, feeble, irregular, finally wholly diaphragmatic.

Alcohol modifies the results of respiration in a constant manner and in all doses. This modification consists in a decrease in the amount of oxygen absorbed and carbon dioxide exhaled. This effect is usually more marked when alcohol is taken fasting than during digestion.

¹ Cited by Peeters, *L'Alcool, physiologie, pathologie, médecine légale*, 1885.

² Henri Toffier found in the brain of a man who died of acute poisoning by alcohol not only alcohol, but also aldehyde: *Considérations sur l'empoisonnement aigu par l'alcool*, Paris, 1880.

³ *Journal of Practical Hygiene*, 4th ed., Lond., 1873.

⁴ David Brodie, *Medical Temperance Journal*, October, 1880.

The influence of alcohol upon the renal secretion is that of a diuretic; but the fact must not be overlooked that this tendency is much increased by the large amount of water which alcoholic drinks necessarily contain. But that alcohol acts as a diuretic, even in small doses and altogether independently of the water with which it is taken, does not admit of doubt. The changes in the urine are qualitative as well as quantitative. The amount of urea, uric acid, and other solids is always notably diminished. The diminution of the amount of phosphoric acid is even greater than that of the nitrogenized substances, especially during the period of excitation.

The diuretic effect of alcohol is dependent upon its direct action on the parenchyma of the kidneys, the qualitative changes in the urine upon its influence on nutrition.

Upon the temperature of the body alcohol has a marked effect. The sensation of warmth experienced after moderate doses is chiefly subjective, and is accompanied by a very slight actual rise in temperature, amounting to some fraction of a degree Fahrenheit, and of but short duration. This rise is followed by a rapid fall, amounting to a degree or more below the norm. This effect is manifested within the course of an hour after the administration, and is of comparatively brief duration, being largely influenced by the condition of the individual at the time as regards mental or physical exercise, digestion, and the like. It is in part due to the increased loss of heat from the surface of the body, favored by more active cutaneous circulation, but chiefly to the action of alcohol in retarding oxidation and the activity of nutritive changes. Toxic doses are followed by marked fall of temperature. The influence of alcohol upon the temperature is more pronounced in febrile conditions than in health.

The influence of physiological doses of alcohol upon the nervous system is, among all its effects, the most marked and the most difficult to describe with exactitude. It is usual to regard this agent as a stimulant and to separate the period of its direct effects into two stages—that of excitement and that of depression. John Hunter defined stimuli as agents which increase some natural action or tendency, in contradistinction to irritants, which produce actions altogether abnormal. Anstie¹ sought to restrict the use of the term stimulant to agents which by their direct action tend to rectify some deficient or too redundant natural action or tendency. Without entering upon the discussion of the doctrine of stimulation, I may say that the views of Anstie have served a useful purpose in making clear some vexed questions. In accordance with these views, the physiological action of alcohol is followed neither by excitement nor by depression, and when its administration is followed by these conditions, its action is not truly physiological, but narcotic or toxic.

The effects of this agent upon the nervous system vary within very wide limits according to innumerable conditions which relate to the temperament, health, habits, occupation of the individual, season, climate, social circumstances, and the quantity, kind of alcoholic drink, and its mode of administration. Its first action in moderate doses and under circumstances free from complications is to increase the functional activ-

¹ *Stimulants and Narcotics*, Lond., 1864.

ity of the brain: the ideas flow more easily, the senses are more acute, speech is fluent, and movement active. These effects accompany the increase in the heart's action, the slight rise in temperature already described, and increased activity of the organism in general. They appear to be in part due to the direct action of the substance upon the cerebrum, and in part to increased activity of the circulation. The effect upon the nervous system has been compared by Nothnagel to the effect, in a higher sphere, of strong moral impulses. Without otherwise modifying existing traits of character, such impulses call them into action, and lead to the accomplishment of deeds quite impossible under ordinary circumstances. To a man worn out by some prolonged task which from sheer fatigue he despairs of finishing, let there be announced some joyful news; he at once feels refreshed, applies himself with renewed energy to his work, and perhaps finishes it with ease. In kind at least this is the effect also of alcohol.

But the limits of the physiological effects are easily transcended, and the manifestations then become those of its toxic influence, between the slightest grades of which and drunkenness the difference is one rather of degree than of kind. These effects must therefore be described under the heading *Acute Alcoholism*.

Passing to the influence of alcohol upon nutrition, we recognize two modes of action. Of these the first is direct and in part local, and results from the stimulation of the glandular apparatus of the mucous membrane of the mouth and stomach, from increased activity of the circulation, and from direct stimulation of the pneumogastric nerve. Hence increased secretion of the digestive juices, augmented appetite, more active peristalsis, and improved digestion, to which, indeed, the direct action of alcohol upon the cerebrum doubtless contributes. It is to these effects that the favorable influences of this agent in the extremes of life, when it is so well borne and so useful, must be largely attributed.

The second mode of action is indirect and general. It has been shown that alcohol diminishes the amount of carbon dioxide expired and of oxygen inspired, that it diminishes the quantity of urea excreted, and that it lowers the temperature of the body. It follows that normal oxidation goes on more slowly—that there is diminished tissue-change. Alcohol supports the body, not by nourishing it as a food, but by curtailing waste; it favors nutrition, not by augmenting the receipts, but by cutting down the expenses of the organism. But nutrition and waste are in health correlated and complementary. They are, in fact, essential and associated processes of life, of which one is not more necessary than the other to the maintenance of health. In various pathological states the arrest of waste is a cardinal indication, and for this purpose alcohol holds the first place. But in health this action itself is pathological, and the beginning of evil. The fat accumulation of the drunkard is due in part to the sugar and starchy matter taken in malt liquors, but much more to this control of waste, as is shown by the fact that spirit-drinkers who have sufficient food also often become fat. Alcoholic excesses tend not only to fat accumulation, but also to fatty degeneration of the tissues. The opinion that alcohol in any dose or under any circumstances is a food in the ordinary acceptation of the term is no

longer tenable. Chauffard has well said: "Not only is alcohol not an aliment; it is the very reverse. Not only does it not contribute to the nutrition of the body; it opposes it and destroys it little by little."¹

THE PATHOLOGICAL ACTION OF ALCOHOL.

I. Acute Alcoholism.

IN accordance with the classification laid down at the beginning of this article, the term acute alcoholism is here used to denote the various forms of primary alcoholic intoxication in contradistinction to the conditions which are brought about by the gradual but long-continued action of the poison, and to the violent and sometimes abrupt outbreaks which are secondary to these conditions. From this point of view, which is at variance with the established usage of writers upon alcoholism, but which is here adopted in the hope that it will tend to simplify the treatment of a subject at present in much confusion, acute alcoholism includes all forms of drunkenness, from mere transient derangement of the normal functions of life, scarcely amounting to tipsiness, to profound intoxication. It includes also poisoning by lethal doses. Chronic alcoholism may be the outcome of frequent repetitions of acute alcoholism at short intervals, or it may result from the constant abuse of alcohol in doses so small that the evidences of its poisonous effects are at no time actively manifested. I hope to be able to show that the seemingly acute outbreaks, the symptoms of which chiefly relate to the nervous system, that occur after the condition of chronic alcoholism is fully established, are commonly preceded for a longer or shorter period by imperfectly developed symptoms of an analogous character, and that these outbreaks differ in essential particulars from acute alcoholism in all its forms.

That persons suffering from some degree of chronic alcoholism may, and as a matter of common occurrence do, after excessive doses suffer from acute alcoholism—in other words, get drunk—is too obvious to demand more than passing consideration at this point; but it is scarcely necessary to point out to those who are familiar with the life-history of such individuals that the time comes when no degree of excess will produce the ordinary manifestations of transient intoxication. It is then that phenomena of another and more serious kind are apt to occur. The difference is that between the reactions of normal or as yet quasi-normal tissues and alcohol on the one hand, and on the other the manifestations induced by the supersaturation of tissues previously alcoholized to the point of an acquired tolerance. This tolerance of the nervous system is in a high degree a pathological condition, and is therefore in an equally high degree

¹ This opinion is at variance with the views generally entertained by English and American writers upon *materia medica*. T. Lauder Brunton (*Textbook of Pharmacology, Therapeutics, and Materia Medica*, Am. ed., 1885) regards "all the evidence as pointing to the fact that alcohol is a food, and in certain circumstances, such as febrile conditions, may be a very useful food; but in health, when other kinds of food are abundant, it is unnecessary, and, as it interferes with oxidation, it is an inconvenient form of food."

unstable and liable to be overthrown by accidents of various kinds as well as by extraordinary excess in alcohol.

The variety of forms and admixtures in which alcohol is taken is so great, and the susceptibility of individuals to its action so different, that it would be a hopeless task to attempt to describe the manifold phases of acute alcoholism. Unfortunately, most of them are too familiar. The following description embraces the more important phenomena, and is intended to serve as a type:

A. THE ORDINARY OR TYPICAL FORM.—The physiological effects of alcohol in moderate doses are followed by no reaction, but they are evanescent. When, however, the dose is repeated at short intervals and the effect is sustained, the condition by its continuance becomes pathological, and the subject enters upon the prodromic period of acute alcoholism. From this condition to that in which the poison manifests its distinctly toxic effects the transition is a speedy one. The face becomes flushed, the eyes brilliant; the heart's action increases in force and frequency; muscular force seems augmented; there is excitation of the mental processes; intelligence seems more active; ideas flow readily; preoccupation ceases; anxieties are forgotten. The future is full of hope, the past has lost its sorrows, its regrets. The powers of expression are brought into fullest play; conversation becomes animated, brilliant, often sparkling and keen. Reason is thrown aside, the judgment relaxed; vanity, pride, rashness, assert themselves. Emotions, sentiments, habitually repressed, are manifested without reserve, often with emphasis and insistence. Hence the proverb, *In vino veritas*.

Then speech degenerates into loquacity; improper confidences are made, indiscretions committed; the bent of disposition is made clear; he who is by nature sad grows sombre, melancholy; he who is irritable becomes cross and quarrelsome; the generous man grows lavish, and a good-natured fellow is everybody's friend. But this intensification of normal characteristics is by no means invariable. Not seldom do we see the timid man become in his cups violent and aggressive, the refined coarse, and the gay melancholy. The sensation of increase in muscular force manifests itself in unusual activity. Gesticulation is frequent, energetic, and apt; there are bodily restlessness and desire to move about. Shouts of laughter, bursts of song, are followed by a disposition to easily-provoked quarrels. At this stage there are evidences of some degree of cerebral congestion. The temples throb, the heart is full, and dizziness is felt. The skin is moist, the mouth pasty, thirst is experienced, and there is frequent desire to pass water. There yet remains some degree of self-control. The phenomena which characterize this condition are more or less transient, and if alcohol be now discontinued they speedily cease, commonly in sleep, sometimes without it, and are followed by sensations of weariness and fatigue, with headache, gastric disturbances, and temporary loss of appetite.

If, however, the influence of alcohol be pushed beyond this point, the manifestations of mere exaltation of function give place to grave perversion of the processes of life. A gradually increasing vertigo is associated with obscured intelligence, dulled imagination, blunted and confused perception, disjointed ideation, and incoherent speech. The recollection grows indistinct, the will purposeless. Now the baser pas-

sions are aroused; evil impulses and illusions of all kinds sway the drunken man. All control of conversation and action is lost. Reason is replaced by delirium, and he becomes a maniac, dangerous alike to himself and to others, liable upon some sudden impulse to commit the most atrocious crimes.

The countenance betrays the profound disturbance of the intellectual and moral nature: its expression is changed, its lines are blurred; the flush deepens, the veins are distended, the arteries pulsate visibly, the gaze is staring, the pupils contracted. The respiration, at first quickened, becomes irregular. The heart's action is rapid and bounding, and sometimes there is palpitation. Somnolence soon deepens into an invincible desire to sleep. At this point great muscular relaxation not infrequently occurs in connection with vomiting, profuse sweating, and dilatation of the pupils.

Muscular movements are irregular and uncertain, the gait vacillating and staggering; the movements of the superior extremities, wanting in precision, become trembling and awkward. At the same time speech becomes embarrassed. Articulation is difficult and imperfectly executed. At length standing becomes impossible; the drunkard, profoundly poisoned, sinks helplessly to the ground, and not infrequently the control of the sphincters is lost. The development of this condition is accompanied by a gradual perversion of general and special sensibility. Dull headache, ringing in the ears, phosphenes, and other disturbances of vision, hallucinations of taste and smell, are followed by abrogation of the special senses. Loss of cutaneous sensibility, beginning at the extremities, invades the whole body, and finally the subject sinks into more or less profound coma, from which it is no longer possible to arouse him. Muscular resolution is complete, sensation is lost; the face is now bloated, deeply flushed, sometimes livid, sometimes ashy pale; the pupils are dilated; the temperature below normal; the respiration stertorous and accompanied by abundant mucous râles. The pulse is feeble, fluttering, the surface covered with sweat, and involuntary evacuations take place.

VARIETIES.—Three varieties of acute alcoholism are recognized by Lentz—the expansive, the depressive, and the stupid. The first is characterized by gayety, self-satisfaction, and content. The drunkard, smiling and happy, is satisfied with the present and full of hope for the future. The second variety is characterized by sadness and melancholy. The drunkard becomes sombre and taciturn; if he talk at all, it is to bewail his misfortunes and to recount his mishaps. In the third variety the period of excitement is wanting and the drunkard passes rapidly into a condition of stupor.

Great as are the modifications of the course of acute alcoholism under different circumstances and in different individuals, it is evident, upon close investigation, that its phenomena—and especially those which relate to the nervous system—manifest themselves in a progressive series more or less constant in the majority of persons. This series includes three well-characterized periods: 1. The stage of functional exaltation of the nervous system; 2. The stage of functional perversion; 3. The stage of depression.

We may, then, recognize the degrees of acute alcoholism corresponding

to these stages.¹ Of these, the first scarcely goes beyond the stage of excitement already described, and if the dose have been moderate or its repetitions not too long continued, the symptoms gradually subside, leaving perhaps no sequels beyond slight headache, tinnitus aurium, some degree of muscular relaxation, and mental depression.

The second degree is characterized by partial abolition of intelligence, of general and special sensation, and of motor power. Hence incoherent speech, extravagant actions, blunted perceptions, hallucinations and delusions, inco-ordination of movements, a reeling gait, and not rarely vomiting and involuntary discharges of urine and feces. This degree of acute alcoholism usually ends in deep sleep with abundant perspiration, to which succeed great lassitude and depression, accompanied by much gastro-intestinal derangement, of which the symptoms are inability to take food, coated tongue, viscid mouth, foul breath, repeated vomiting, and occasionally diarrhoea. These sequels are less serious in those individuals accustomed to excesses than in others.

In the third degree the subject falls by gradual stages or abruptly into more or less profound coma. The abolition of intelligence, sensation, and motion is complete. The face is now swollen, livid, or pale, the pupils dilated, the respiration stertorous, the pulse feeble, often slow, sometimes imperceptible, the surface cool and often bathed in sweat. The man is dead drunk. The symptoms are now of the gravest kind. It is no uncommon occurrence for this condition to end in death.

Well characterized as these three degrees of alcoholic intoxication are, they are not, when occurring successively in the same individual, separated by abrupt lines of demarcation. On the contrary, the evolution of the symptoms is from the beginning to the close a gradual and progressive one.

While the scope of this article precludes extended discussion of the symptoms of acute alcoholism—which, indeed, present an almost endless variety in their intensity and combination—yet it seems necessary to the elucidation of the subject to point out some of the more prominent modifications due to variations in the conditions under which alcohol acts upon the organism.

First among these are differences in the nature and composition of the drink. Here we have to do not only with the well-known differences in alcoholic beverages, as spirits, wines, and malt liquors, and their quality and grades, but also with differences in the chemical nature of the alcohols themselves which enter into their composition. The principal of these alcohols are—

Methyl alcohol, CH_3OH .
 Ethyl alcohol, $\text{C}_2\text{H}_5\text{OH}$.
 Propyl alcohol, $\text{C}_3\text{H}_7\text{OH}$.
 Butyl alcohol, $\text{C}_4\text{H}_9\text{OH}$.
 Amyl alcohol, $\text{C}_5\text{H}_{11}\text{OH}$.

Richardson was the first to call attention to the differences in the physiological and pathological action of the members of this series. Other

¹ These stages correspond to the three degrees of alcoholic intoxication recognized and described by German writers as *Rausch*, *Betrunktheit*, and *Besoffenheit*. To these may be added the prodromic period, designated as *Weinwarmer Zustand*. These three degrees are known to the French as *l'ivresse légère*, *l'ivresse grave*, and *l'ivresse suraiguë*.

observers, among whom may be named Dujardin-Beaumetz and Andigie,¹ and Rabuteau,² have also investigated the subject. The researches of these observers have established the fact that the effects of the different alcohols in depressing the temperature of the body and in paralyzing sensation and motion are exactly the same, but that their narcotic influence upon the nervous system increases, dose for dose, in proportion to the amount of carbon which they contain. Ethyl alcohol is, with the exception of methyl alcohol or wood-spirit, the least rich in carbon and the least dangerous to health.³ The increased consumption of alcohol, both as a beverage and in the arts, the demand for cheap, coarse spirits producing their primary narcotic effects with promptness, and the cupidity of manufacturers, have led to the almost universal adulteration of the liquors of commerce with the more dangerous alcohols.⁴ So extensive has this substitution of the high-carbon alcohols for ethyl or ordinary spirit of wine become that it has been suggested that alcoholism should be divided into ethylism, amylism, propylism, and butylism—not so much for clinical reasons as to direct attention to the composition of alcoholic drinks and to their deleterious properties.⁵

The effects of propyl, butyl, and amyl alcohols upon the nervous system are not only more marked than those of ethyl alcohol, but they are more rapid. The stage of excitement is speedily induced, and its manifestations are intense. Hence the preference often manifested by drunkards for cheap, coarse spirits. On the other hand, the stage of depression quickly follows, and is itself of relatively shorter duration than that induced by ethyl alcohol, probably for the reason that the amount required to bring it about is smaller. Muscular resolution soon becomes general and complete; insensibility speedily succeeds; the fall of temperature is rapid; vomiting, occasionally absent in the intoxication produced by ethyl alcohol, is the rule, and is frequently repeated. Muscular tremor—and especially is this true of amyl alcohol—comes on earlier, is more general and more marked, and lasts longer than that which occurs in consequence of excess in ethyl alcohol. Richardson states that the complex alcohols are more slowly eliminated than ethyl alcohol, but the French observers are of a different opinion.

But these differences in action are probably rather differences in degree than in kind. Peeters says: "Ethyl alcohol is less dangerous than the more complex members of the series. It is less irritating, less charged with carbon, its specific gravity is less, its fumes are less dense and escape

¹ *Recherches expérimentales sur la Puissance toxique des Alcools*, Paris, 1879.

² "Contributions à l'Étude des Effets physiologiques et thérapeutiques d'Alcool," *Compt. rend. Société de Biologie*, 1870-71.

³ "Methylic alcohol is the safest of the series of bodies to which it belongs" (B. W. Richardson, *Lectures on Alcohol*).

⁴ M. Girard, chief of the municipal laboratory in Paris, has recently called attention to the enormous diminution in the production of alcohol by the natural method—that is to say, by the distillation of wine. The falling off he ascribes to the ravages of the phylloxera. This loss is made up by the substitution of spirits obtained by the distillation of various fermented grains, potatoes, beets, molasses, etc. To give some idea of the extent to which the alcohols of industry at present replace the alcohols of wine, he cites the following figures: From 1840 to 1850 the mean annual production of alcohol in France was 891,500 hectoliters, of which the alcohols of wine amounted to 715,000 hectoliters. In 1883 the product reached 1,997,280 hectoliters, of which alcohols obtained by the distillation of wine amounted to only 14,678 hectoliters.

⁵ Peeters, *L'Alcool*, 1885.

more readily from the economy ; its action ought to be less profound, less prolonged, than that of butyl, propyl, and amyl alcohol, but it is of the same nature. It is not qualitatively but quantitatively different. I suspect that the effects of liquors containing ethyl alcohol are, as a rule, less decidedly injurious, by reason of the more favorable surroundings of those who can afford to use them."

The three principal groups of the alcoholic drinks of commerce produce, independently of the properties of the different kinds of alcohol which they contain, forms of acute alcoholism which differ in important respects.

The intoxication induced by the exclusive use of malt liquors is dull and heavy, slow in coming on, and of long duration. The stage of excitement is relatively brief, not often characterized by gayety, often brutal ; drowsiness soon supervenes and deepens slowly into unconsciousness. The after-effects are disagreeable and prolonged. The enormous quantity of fluid and the large amount of malt extractives cause gastro-hepatic derangements of a more or less distressing kind. To the hops must be ascribed the prolonged dullness which is so characteristic of the after-effects of beers and ales. The influence of the various substances used in the adulteration of beers without doubt modifies the symptoms of the alcoholism which these beverages cause when impure. These substances consist of glucose, various vegetable bitters, and salt—articles not necessarily hurtful in small amounts, but capable of exerting deleterious action when taken in excess and in connection with the normal ingredients of beer.

The intoxication produced by pure wines is, as a rule, characterized by a bodily and mental activity strongly in contrast with the drunkenness produced by malt liquors. The drunkard is usually gay and vivacious—at all events, lightly merry or not hopelessly despondent. His mood is variable, changing from grave to gay. The first stage is prolonged, and the manifestations of the later stages less grave, nor are the sequels apt to be so severe. The action is that of ethyl alcohol and certain ethereal substances, the latter being present, however, only in minute amounts. The rapidity of the effects depends upon the proportion of alcohol which the wine contains, which varies from about 7 per cent. in the clarets to 15, to 18, or even to 20 per cent. in port and madeira. The sparkling wines, moselle and champagne, produce more transient effects than the still wines—a fact probably to be explained by their greater and more prompt diuretic action.

The foregoing remarks apply only to pure wines. The intoxication which follows the use of artificial compounds sold in all parts of the world as wines betrays in its course and symptoms the high percentage and toxic characters of the mixed alcohols which form their essential ingredients.

The intoxication which follows excesses in the various spirits of commerce presents no special characters. Its symptoms are determined to a considerable extent by the relative purity—that is, freedom from admixture with the various complex alcohols—of the liquor by which it has been produced. Potato spirit causes drunkenness which is profound, overwhelming, and preceded by a brief period only of excitement.

Even more important than the kind of liquor is its quantity. Here,

however, it is impossible to formulate precise statements. A few glasses of wine will produce effects in some persons more decided than much strong spirits in others. Those conditions which favor the absorption of alcohol hasten the production and augment the intensity of alcoholism; and the contrary is true. Thus, alcohol taken while fasting does much more harm than the same amount taken with a meal. Intense excitement, anger, mortification, or other violent emotion is said by Lentz to increase the effects of alcohol. Sudden transition from a warm to a cold atmosphere intensifies the action. That this effect of cold is due to suppression of perspiration, and the consequent interference with one of the elements of elimination, is much less likely than that it is due to the further depressing influence of cold upon the nervous system, already depressed by the alcohol imbibed. Occupation has in an indirect way much to do with the facility with which alcohol is borne. Hard work, requiring great and continuous muscular effort, especially in the open air, diminishes the liability to acute alcoholism, while sedentary occupations and confinement strongly predispose to it. These well-recognized facts are to be accounted for by the influence of different occupations and modes of life upon the elimination of the poison. Persons who are debilitated by chronic disease or are convalescent from acute maladies, and the otherwise feeble and anæmic, are peculiarly obnoxious to the action of alcohol. Previous custom and hereditary peculiarities of organization exert an influence upon the liability of individuals to acute alcoholism, and upon its nature when induced.

Persons of an impressible nervous organization are peculiarly prone to the evil effects of drink. With such persons slight excess is often followed by serious consequences; the intellectual disturbance is early developed and out of proportion to the derangements of motility and sensation. The effects of alcohol are manifested more promptly and more intensely in children and women than in men or in the aged. Drunkenness is induced more rapidly and with smaller quantities of alcohol in summer than in winter, in warm than in cold countries.

*B. IRREGULAR FORMS OF ACUTE ALCOHOLISM.*¹—1. *The Maniacal Form.*—The outbreak is usually sudden, sometimes occurring after the ingestion of comparatively small quantities of alcohol; at others after excesses which in a certain proportion of the cases have already ceased. The transition from a condition apparently normal, or marked at most by mental concentration, restlessness, and some degree of irritability, to furious mania is sometimes almost instantaneous, and the subsidence of the latter no less swift. More commonly there are prodromic symptoms, among which are general malaise, præcordial distress, palpitations, flushing of the face, vertigo, tinnitus aurium, phosphenes, and dull, throbbing headache. The attack is characterized by maniacal excitement, usually of a furious kind. The restlessness is, however, far from being aimless and purposeless. On the contrary, impelled by the wildest passions, transported with rage, the patient seeks the destruction of life and property, and wreaks his fury alike upon animate and inanimate objects. So great is his strength for the time being that several strong men may be scarcely able to restrain him. He pours forth a torrent of commingled threats and curses, in which may be heard unintelligible, and often inar-

¹ *Ivresses anormales ou pathologiques* of the French writers.

ticulate, sounds. He is beside himself, yet, so far as can be learned, there are neither hallucinations nor delusions by which his fury can be explained. In this respect the condition is wholly unlike that form of alcoholic mania in which the actions are explained by the imaginary surroundings and circumstances of the patient. In the maniacal form of acute alcoholism the most trifling incident, a word, a look, are sufficient to produce a tempest of rage that may end in scenes of violence. Nevertheless, the patient yet retains for a time some notion of his surroundings. At length, however, he falls into a state of complete unconsciousness, and the delirium is like that of fever, of the delusions of which no recollection afterward remains. This form of acute alcoholism is almost invariably associated with the symptoms of a high degree of cerebral hyperæmia. The hands are hot, the eyes injected, the pupils dilated or contracted, the expression eager. There are abundant secretion of saliva, frequent and irregular respiration, a rapid pulse—often exceeding 100—throbbing arteries, distended veins, and a hot skin, often bathed with sweat. The urine is scanty and constipation usual. There is, as a rule, increased sensibility to light and sound. The attack is liable to come to a tragic close in murder or suicide.

The termination of the paroxysm is as abrupt as its onset. Some abatement of its violence is quickly followed by signs of mental and bodily exhaustion; this deepens into profound sleep, which often lasts from twelve to twenty-four hours, and from which the patient awakes clear, tranquil, and as if nothing had happened, or dimly recollecting the occurrences that have passed as a hideous dream. In a small proportion of the cases the sleep deepens into coma which ends in death.

2. *The Convulsive Form.*—The analogy to the form just described is very close. Here, however, the morbid manifestations directly relate to the muscular system. The attack is commonly sudden, often abrupt. When prodromes occur, they are such as have been described as preceding the maniacal form—mental irritability, headache, præcordial distress, etc. The attack is thus described by Lentz: "The phenomena consist not in ordinary convulsions, but in convulsiform movements of remarkable disorder, only to be compared with the extraordinary convulsive movements of grave hysteria. We have happened to see several cases during the attack. These patients threw themselves to the ground, giving themselves up to the most irregular and disorderly contortions, rolling from side to side, throwing the body into the air, striking out with the legs and arms, kicking at random, biting at persons and things—now knocking the head against the floor, again rising for a moment, only to fall back and commence again the same contortions. Their movements are energetic and violent. There are madmen whom it is dangerous to approach by reason of the violence of their movements, but they are certainly much less dangerous than those suffering from the maniacal form of acute alcoholism, for their morbid motility has no tendency to take the shape of co-ordinated actions. It is movement wasted in pure loss. Their muscular energy is excessive; it is difficult to restrain them. To resume: the peculiarity of these movements is this, that they are not intentional, but that they are rather purely convulsiform, automatic.

"Another phenomenon of this form, one of its characteristic symptoms, is the state of intellectual enfeeblement which accompanies it. The loss

of consciousness is complete, and were it not for the movement produced by the convulsions the patient would be plunged into a condition of profound coma. He has not the least knowledge of himself; not even delirium denotes intellectual activity; only an occasional harsh cry or inarticulate sound indicates the existence of mind."

The other symptoms differ but little from the maniacal form. The duration of the attack varies from a few hours to half a day; its termination is usually abrupt, the patient falling into a condition of extreme exhaustion with stupor, or into a deep and prolonged sleep, from which he awakens without the slightest recollection of the attack through which he has passed.¹

3. *Acute Alcoholism in Persons of Unsound Mind.*—The insane, imbeciles, epileptics, and persons suffering from nervous diseases are, as a rule, abnormally susceptible to the action of alcohol, and present more or less striking peculiarities in the symptoms which it causes. Brief notice of certain of these peculiarities is in accordance with the scope and plan of this article.

In general paralysis propensity to alcoholic excesses is not rarely an early symptom. The subject is very susceptible to the action of alcohol, and under its influence rapidly passes into a state of intense excitement, characterized by incoherence, delirium, excessive restlessness, and unwillingness to seek repose until exhaustion is complete. It is under the influence of this easily-provoked alcoholic excitement that the vagabondage, quarrels, thefts, robberies, incendiarisms, and other grave crimes observed during the first stage of this form of insanity are often committed.

Imbeciles and idiots are likewise quickly, and often intensely, excited by alcohol. They are then apt to be quarrelsome, perverse, and ungovernable, defiant of authority, and capable of shocking crimes, often evincing latent vicious tendencies previously wholly unsuspected.

Epileptics are easily affected by alcohol, and usually violent in the stage of excitement; not rarely this period terminates in a true epileptic seizure.

The drunkenness of the dipsomaniac is characterized by a prolonged, uninterrupted stage of excitement without the stage of depression. Such individuals are capable of consuming in their periodical excesses large amounts of drink without the evolution of the ordinary successive phenomena of acute alcoholism.

Persons of unsound mind are, as a rule, so susceptible to the influence of alcohol, and suffer so promptly and intensely from its primary effects, that they are rarely able or permitted to consume a sufficient quantity to bring about a comatose state.

The irregular forms of acute alcoholism are only to be explained by the inherited or acquired constitutional peculiarities of individuals. To attempt to explain them in any case by the quality of the alcohol by which they are induced meets with the difficulty indicated in the fact that they are isolated and comparatively rare, even where the coarser spirits are habitually consumed. They occur in individuals who habitually commit excesses, but they cannot be viewed as manifestations of chronic alcoholism, for the reason that they also occasionally occur in those who are

¹ Consult also *Dict. des Sciences méd.*, t. xxvi.

not habitual drinkers, and even in persons who have not for a long time previously tasted strong drink. Furthermore, as has been pointed out, they are not only occasionally, but indeed even as a rule, induced by relatively small amounts of alcohol. They are then the manifestations of idiosyncrasy. One of the striking peculiarities of this peculiar bodily organization is this very susceptibility to the action of alcohol in doses smaller than are taken with impunity by ordinary individuals. It is also characterized by a special tendency to delirium in febrile states, to hallucinations, to disturbances from trifling changes in climate, food, or manner of life, to irritability of the nervous system, and in particular of the vasomotor system, and by a tendency to convulsions. With these tendencies is associated an unstable mental and moral character. Such persons are liable to headaches, vertigo, and epistaxis—signs of cerebral hyperæmia, which is easily induced—and their family histories indicate strong hereditary tendencies to neurotic disorders, and not rarely addiction to alcohol on the part of one or several ancestors.

But this idiosyncrasy is by no means always an inherited one. It is acquired as one of the results of profound disturbance of the nervous system, such as is produced by moral causes, by temporary or recurrent insanity, by wounds and injuries of the head, by the infectious diseases, especially syphilis, enteric and typhus fever, and small-pox, and by inflammations of the meninges.

What may be the precise mode of action of alcohol in the production of its acute effects yet remains a matter of conjecture. It cannot be doubted that its primary and direct action is upon the nervous system, and that the circulation is secondarily but rapidly implicated. But it is quite impossible to say, in the present state of knowledge, what this action is. It has been suggested that certain chemical modifications of alcohol in the blood, or of the blood itself in the presence of alcohol, cause these phenomena; that aldehyde is the active agent in their production; that the chemical changes by which alcohol is transformed into aldehydes, acetic acid, and finally into carbon dioxide, deprive the blood of the oxygen necessary for the proper performance of the functions of the nervous system. Unfortunately for these views, neither the presence of aldehydes in the blood in acute alcoholism, nor these transformations themselves, have yet been demonstrated, and a high degree of deoxygenation of the blood is frequently observed in asphyxia, the inhalation of nitrous oxide, etc., without the train of symptoms characteristic of the condition now under consideration.

It is more than probable that varying conditions of the cerebral circulation, secondary in themselves, have much to do in the causation of certain symptoms. The experimental investigations of Bernard and others have established the fact that during the period of excitement there is actual congestion of the meninges. This condition is transient, and reproduced after each repetition of the dose. After a time, or if the dose at first be excessive, the congestion is succeeded by anæmia.

PATHOLOGICAL ANATOMY.—Upon the examination of the bodies of persons who have died by accident while drunk or in consequence of drunkenness itself, deep congestion of the cerebral meninges, and especially of the pia, has been almost constantly observed. In the pia effusions of blood are occasionally encountered. The condition of the cerebral

substance is not always the same. It is in a majority of the cases more or less deeply congested, yet it presents in other instances no appreciable departure from the normal state, and in a smaller number still there is actual anæmia.

The sinuses and choroid plexuses are distended with dark blood; the cerebro-spinal fluid is increased, and often tinged with blood; the ventricles are distended with fluid, which not rarely has an alcoholic odor. Occasionally the ventricles contain blood, and hemorrhage into the substance of the brain has been observed.

The condition of the elementary nervous tissues after death from acute alcoholism is not yet known.

The lungs are deeply congested, with small extravasations of blood into their substance, and often œdematous. Congestion of the liver, spleen, and kidneys in varying degrees of intensity is also seen. The pancreas is usually deeply injected, occasionally the seat of large extravasations of blood. The mucous membrane of the stomach is invariably deeply injected when the alcohol has been introduced into the organism in the ordinary manner. The observation of Caspar that post-mortem decomposition takes place with diminished rapidity has been denied by Lancereaux and others.

Other post-mortem conditions appear to be neither constant nor characteristic. The stomach usually contains partially digested food and alcohol. Lallemand, Perrin, and Du Roy observed, both during life and after death, in the blood of animals subjected to experiments, great numbers of minute glistening points, which upon microscopic examination proved to be fat-globules. The same condition has been observed in man, not only when death has taken place owing to acute alcoholism, but also when it has occurred during the digestion of a hearty meal without alcohol. The blood itself is often fluid and dark-colored; the heart sometimes empty, sometimes containing a few soft clots. Tardieu¹ states that in sudden death during drunkenness pulmonary apoplexy and meningeal apoplexy, if not constant lesions, are at least extremely frequent, and almost characteristic. Baer, on the other hand, denies the occurrence of specific or characteristic lesions.

C. ACUTE POISONING BY ALCOHOL IN LETHAL DOSES.—The symptoms are much modified when overwhelming doses of strong alcohol are introduced into the organism at once or in the course of a short time. Here alcohol produces death as an acute poison. The cases may be arranged in two groups:

1. *Corrosive Poisoning.*—These cases are very rare. They are caused only by undiluted alcohol, and depend upon the action of this agent in coagulating albumen and disorganizing the tissues with which it comes in contact by its affinity for the water which they contain. Absolute alcohol is a powerful corrosive poison. It produces intense phlegmonous inflammation of the œsophagus and stomach, with erosion of the mucous membrane, accompanied by vomiting, diarrhœa with bloody stools, prostration, and stupor. Death occurs by heart-failure. Among the direct effects of large doses somewhat less concentrated are acute and subacute gastritis with characteristic symptoms.

¹ "Observations médicales sur l'État d'Ivresse," *Annales d'Hygiène publique et de Médecine légale*, tome xl.

Percy¹ injected by means of an œsophageal tube 90 grammes of absolute alcohol into the stomach of a dog. Death followed in the course of eight hours in consequence of violent gastro-intestinal inflammation with ulceration. Dujardin-Beaumetz and Andigie found the gastric and intestinal mucous membrane of dogs poisoned by alcohol, red, deeply injected, and "presenting at certain points a black coloration due to effused blood." This fact they regard as worthy of note, because in their experiments the toxic agent was introduced, not by the mouth, but hypodermically, and they explain it by the supposition—which appears to me warrantable—that it is due to elimination by the mucous glands. Hence the congestion, softening, and hemorrhage.² These observers also found that the symptoms were more acute and the lesions more marked when poisoning was caused by propyl, butyl, or amyl alcohol than when it was produced by ethyl alcohol.

2. *Acute Narcotic Poisoning*.—Much more common are the cases in which death is rapidly produced by excessive doses of ordinary diluted alcohol taken at once or rapidly repeated. This happens under various circumstances, as when a drunkard avails himself of some favorable opportunity to gratify to the full a bestial appetite, or upon a wager drinks a number of glasses of spirits in quick succession or a given quantity down, or when a man already drunk is plied by his companions for pure deviltry. Suicide by this means is, in the ordinary sense of the term, rare, and murder still more so. The latter crime has, as a rule, been committed upon infants and children. Blyth³ estimates the fatal dose of absolute alcohol, diluted in the form of ordinary whiskey, gin, etc., at from one to two fluidounces for any child below the age of ten or twelve years, and at from two and a half to five ounces for an adult. In the instance recorded by Maschka⁴ two children, aged respectively nine and eight years, took partly by persuasion, afterward by force, about one-eighth of a pint of spirits of 67 per cent. strength—about 1.7 ounces of absolute alcohol. Both vomited somewhat, then lay down. Stertorous breathing at once came on, and they quickly died. Taylor relates a case in which a quantity of brandy representing about two fluidounces of absolute alcohol produced death in a child seven years old.

The symptoms are uniformly the same. The period of excitement is transient or absent altogether; occasionally the patient falls at once to the ground while in the act of drinking or immediately thereafter; complete coma, interrupted by shuddering convulsions, may terminate in the course of a short time in death. If the fatal issue be delayed, there are vomiting and involuntary discharges; the respiration becomes slow, embarrassed, stertorous; the heart's action is feeble and irregular, the pulse almost or wholly imperceptible; the temperature rapidly falls several degrees: 90° F. has been observed. The pupils are dilated; insensibility and muscular resolution are complete. The face is bloated, cyanotic; the sur-

face bathed in a clammy sweat; the mucous membrane of the mouth often swollen and blanched. Vomiting is usual, but not constant, and there is occasionally thin mucous diarrhoea, the stools being mixed with blood. If the patient survives any considerable length of time, acute superficial gangrene of the parts most exposed to pressure is liable to take place. Recovery is rare; its possibility is, however, increased in proportion as the subject is of vigorous constitution, previous sound health, beyond the period of childhood, not yet approaching that of physiological decadence, and as treatment is early instituted and carried out with judgment.

The diagnosis is difficult, almost impossible, in the absence of witnesses: it is rendered still more obscure by the fact that this, as other forms of alcoholic coma, may be complicated by cerebral or meningeal hemorrhage and by cerebral congestion, in themselves fatal—lesions the onset of which may have been the cause of mental aberration leading to the commission of impulsive alcoholic excesses.

The prognosis, in the highest degree unfavorable in all cases, is rendered yet more so by the occurrence of intense cerebral and pulmonary congestions.

The lesions found post-mortem are those of acute alcoholism, already described. As this form of alcoholic poisoning frequently occurs in the subjects of chronic alcoholism, the lesions of that condition are often encountered, and must be distinguished from those due to the lethal dose. Nor must we overlook the fact that in the action of alcohol just described we have to do with a process differing from ordinary acute alcoholism in degree rather than in kind—a consideration which tends to simplify our notions of the pathology of alcoholism in general.

II. Chronic Alcoholism.

The prolonged abuse of alcohol brings about a series of changes which affect alike the organism at large and its various structures. The changes thus brought to pass are of the most varied kind, and depend upon individual differences too manifold and complex for enumeration and classification. Among the more important of these individual peculiarities are those which relate to temperament, constitution, hereditary predisposition, occupation, social position, personal habits, tendency to or already-existing disease of particular organs and systems, and the like. The degree of the pathological change is determined by the strength and quantity of alcohol consumed and the duration of habitual excess. The human body is capable of adapting itself to the habitual consumption of large quantities of alcohol, just as to other directly acting agents of an injurious nature, such as foul air, bad drinking-water, and unwholesome food, or even to the action of substances dangerous to life, as opium or arsenic, and yet presenting for a considerable time the appearance at least of health. Degeneration of the tissues of the body and disorders of its functions are nevertheless surely produced. These alterations are not the less dangerous to health and life because they are insidious and remain for a time latent. Furthermore, like the habit of which they are begotten, they are progressive, and sooner or later declare themselves in open disease.

The condition, whether latent or manifest, that is produced by prolonged habitual alcoholic excess is designated chronic alcoholism.¹

The symptoms of this condition, when fully established, differ within wide ranges in kind and degree. They are the manifestations of derangements of the viscera, of the nervous system, and of the mind. Varying among themselves according as the stress of the pathological action has fallen upon one organ or another, forming combinations at once curious and inexplicable, developing quietly, without event, almost imperceptibly at one time, breaking into the most furious paroxysms at another, they present for our study perhaps the most complex of chronic morbid conditions. The chronic alcoholism which is latent is not, therefore, always without symptoms. They are, however, often slight and escape observation, or when manifest they are not infrequently ascribed to other causes; or, again, their etiological relations being concealed or overlooked, they are exceedingly obscure and puzzling. This is especially the case in the chronic alcoholism produced by the secret tipping of otherwise respectable persons, and especially women.

To facilitate description, we shall consider the derangements of the viscera, the nervous system, and the mind in regular order, according to the scheme on p. 514. But the reader will observe that whatever may be the prominence of particular symptoms or groups of symptoms in any given case, all parts of the organism are involved, and that there is no such thing as chronic alcoholism restricted to any particular viscus or group of viscera, to the nervous system, or to the mind.

A. VISCERAL DERANGEMENTS.—There is nothing specific in the lesions of chronic alcoholism. The chronic hyperæmia, steatosis, and sclerosis induced by alcoholic excesses differ in no respect from those conditions brought about by other causes. That which is specific is the evolution of a series of morbid changes in the different structures of the body under the influence of a common and continuously acting cause. The digestive system is affected, as a rule, long before the vascular or the nervous system.

1. Local Disorders.—*a. Disorders of the Digestive System.*—**The Mouth and Throat.**—The action of insufficiently diluted alcohol upon the mucous tissues is that of an irritant. The habitual repetition of this action causes subacute or chronic catarrhal inflammation. The condition of the tongue varies with that of the stomach. The mouth in acute alcoholism is apt to be pasty and foul, the tongue slightly swollen and coated with a more or less thick yellow fur; there is often also an increase of saliva; in chronic alcoholism the tongue is usually small, sometimes red, sometimes pale, often smooth from atrophy of the papillæ, not rarely deeply fissured. In a word, the condition of this organ is that seen in the various forms of subacute or chronic gastritis. The salivary secretion is often notably diminished, the sense of taste impaired. Relaxation of the throat and

¹The writer, although fully aware of its imperfections, regards the above definition of the term as more in accordance with the present state of our knowledge of the subject, and therefore more useful, than any other that he has been able to find. It is scarcely necessary to repeat here that the restriction of the term chronic alcoholism to accidental or occasional manifestations of a permanent state is misleading and unscientific. The same criticism is applicable to the attempt that has been made to establish this condition as a substantive disease, chronic, progressive, and characterized anatomically by inflammatory, sclerotic, and steatogenous processes.

uvula and granular pharyngitis are common. Those who, whilst leading a sedentary life, are inclined to the pleasures of the table and a free indulgence in spirituous liquors often suffer from these affections, Mackenzie¹ states that the worst cases of chronic catarrh of the throat generally arise from the habitual abuse of the stronger forms of alcohol. The associated influence of tobacco in the causation of this group of affections is not to be disregarded.

Lancereux encountered ulceration of the œsophagus, and Bergeret a case of narrowing of that organ, in chronic alcoholism.²

The Stomach.—In addition to functional dyspepsia, which is scarcely ever absent in chronic alcoholism, all forms of gastritis, from simple erythematous inflammation of the mucous membrane to sclerosis and suppurative inflammation of the stomach, are encountered. Armor³ assigns to the habit of spirit-drinking, especially to the habit of taking alcohol undiluted on an empty stomach, a high place among the causes of indigestion. He regards this habit as a prominent factor in the production of chronic gastric catarrh—a condition very frequently present in indigestion. This observer also regards the excessive use of alcohol as the most frequent among the direct exciting causes of gastric inflammation in this country, exclusive of acid or corrosive poisons. Next to errors in diet as a cause of chronic gastritis he places the immoderate use of alcohol, especially by persons whose general health and digestive powers are below a healthy standard. The primary lesions are vascular dilatation and hyperæmia. The mucous membrane is discolored, red or bluish, in scattered patches of varying size, with occasional ecchymoses of a bluish hue or spots of pigmentation. These patches occupy more commonly the region of the cardia and the lesser curvature. Vascular injection is conspicuous; the veins are dilated, tortuous; the mucous glands hypertrophied; the surface covered with thick, ropy, acid-smelling mucus. After a time permanent changes in the mucous membrane are set up. It undergoes atrophy or softening; or, again, it becomes hardened, thickened, and contracted, its rugæ more prominent, its surface mammilated—sclerosis. Grayish-brown pigmentation, the remains of former blood-extravasations, is seen at many points. Minute retention-cysts are formed in consequence of the occlusion of the ducts of certain glands. The submucous connective tissue and the muscular coat occasionally undergo, in consequence of prolonged gastritis, local hypertrophy.

Acute suppurative inflammation of the stomach, with purulent infiltration of, or the formation of abscesses in, the submucous tissue, has been met with in drunkards. It is extremely rare, and results from the violent irritant action of large doses of strong alcohol in subjects debilitated by previous excesses.

Gastric ulcer is much more common. The abuse of alcohol is regarded as an indirect cause of this lesion by the majority of writers. In the present state of knowledge alcohol as usually taken can scarcely be regarded as a direct cause of ulceration. Nevertheless, gastric ulcer is relatively

¹ *Diseases of the Pharynx, Larynx, and Trachea*, 1880.

² Peeters regards it as probable that the connective-tissue hyperplasia and resulting stenosis seen in the stomach as a result of the action of alcohol may also occur in the œsophagus.

³ See this *System of Medicine*, Vol. II. pp. 446, 464, 470.

common in alcoholic subjects. Leudet¹ found gastric ulcer in 8 of 26 necropsies of drunkards. Baer and Lentz also regard the abuse of alcohol as a very common cause of ulceration. The ulcers are usually superficial, occupy by preference the neighborhood of the cardia and the lesser curvature, and are apt to be multiple. In these respects they differ from simple gastric ulcer. The latter lesion is also probably as frequent, if indeed not more frequent, in individuals dying of chronic alcoholism than in others.

The view formerly entertained that alcohol was an important cause of cancer of the stomach has been shown by Kubik, Magnus, Huss, Engel, and others to be untenable. Carcinoma ventriculi is rarely associated with chronic alcoholism.

The dimensions of the stomach are rarely normal. Dilatation is usually present in the early stages, and in beer-drinkers throughout; in the advanced course of alcoholism due to spirit-drinking the organ undergoes, in consequence of changes secondary to prolonged inflammation, more or less contraction, which is in many cases irregular.

Dyspeptic symptoms are common: the appetite is variable, irregular, and at length wholly lost. There is especially distaste for food in the morning. This, together with the disordered state of the secretions of the mouth and a feeling of nervous depression on rising, leads to the disastrous habit of taking spirits early in the day. Gastric digestion is performed with difficulty; it is accompanied by sensations of distension and weight, by flatulence and acid eructations. Heartburn is a common symptom. The drunkard is not rarely tormented by an uneasy craving or sense of emptiness in the region of the stomach, which he temporarily allays by nips and pick-me-ups and morsels of highly-seasoned foods at odd times, with the result of still further damage to his digestion and the complete loss of appetite for wholesome food at regular hours. In the course of time the characteristic morning sickness of drunkards is established. On arising there is nausea, accompanied by vomiting—sometimes without effort or pain, at others attended by distressing retching and gagging. The matter vomited consists usually of viscid mucus, at first transparent, then flaky, and at length, if the efforts be violent, of a green or yellow color from the admixture of bile. These symptoms ordinarily do not recur until the following day. In other cases vomiting is more frequent, recurring at irregular periods during the day, and not uncommonly an hour or two after the ingestion of food. When gastric ulcer is present, portions of the vomited matter are often dark and grumous like coffee-grounds or the settlings of beef-tea, and are found upon microscopic examination to contain blood-corpuscles. Actual hæmatemesis may also occur under these circumstances, and be repeated from time to time. The quantity of blood thrown up is frequently small; at times, however, it is excessive, and occasionally so great as to cause death.

Common as are the evidences of gastric disturbance in chronic alcoholism, they are far from being constant, and it is worthy of note that in proportion to the number of the cases serious gastric affections are, except in the later stages, relatively infrequent.

The Intestines.—Lesions of the small intestine due to alcoholism are

¹ *Clinique médicale de l'Hôtel Dieu à Rouen, 1874.*

extremely rare. Even when simple or ulcerative inflammation of the stomach is localized at, or extends to, the pylorus, it rarely passes any great distance into the gut. The large intestine is, on the contrary, frequently the seat of chronic inflammatory processes. Here we find vascular engorgement, patches of pigmentation, localized thickening of the mucous and sub-mucous tissues, enlargement of the solitary glands, and an excessive secretion of viscid mucus. The tendency to permanent vascular dilatation, which is a characteristic result of alcoholic habits, constitutes a powerful predisposing influence in the causation of hemorrhoids, which are common. Alcohol acts directly upon the hemorrhoidal plexus of veins, and indirectly by causing permanent congestions of more or less intensity in the greater number of the abdominal viscera. When a prolonged course of excesses in alcohol has led to chronic congestion with hypertrophy, cirrhosis, or other structural change in the liver which is capable of causing permanent mechanical obstruction of the portal circulation, hemorrhoids constitute a very common affection in the group of morbid entities secondary to these conditions.

The symptoms of intestinal derangement are in the beginning, as a rule, slight and occasional. They consist of uneasy sensations or colicky pains in the abdomen, a feeling of fulness with or without tympany, and constipation alternating with diarrhœa: in a word, they are the symptoms of acute or subacute intestinal indigestion terminating in an attack of intestinal catarrh. Attacks of this kind repeat themselves in a considerable proportion of the cases with variable but increasing frequency, until at length the conditions of which they are the expression become permanent, and the patient suffers, among other distressing symptoms hereafter to be described, from chronic diarrhœa. The stools are now of the most variable character—occasionally bilious, sometimes containing small dark scybalous masses, rarely formed, but usually containing more or less abnormal mucus, too much fluid, and traces of blood. Indeed, at this stage several causes—among which I may mention visceral congestions, local inflammation of the intestinal mucous membrane, dilatation of the hemorrhoidal veins, and structural changes in the liver—conspire to determine blood toward the interior of the intestinal tube. Traces of blood in the stools are therefore frequent, and actual hemorrhage and the appearance of the dark, tarry, and altered blood formerly described under the term *melæna* are by no means rare. Colliquative diarrhœa and dysenteric attacks also occur, and at length an intense enteritis with uncontrollable diarrhœa may end the life of the patient. The conditions just described lead to rapid emaciation, and contribute when present to the establishment of the cachexia so marked in many cases of chronic alcoholism.

The Glands.—The salivary glands were found by Lancereaux¹ to have undergone softening, with granulo-fatty changes in their epithelium. If such changes are among the usual effects of alcohol, they are doubtless productive of alterations in the saliva, which explain, in part at least, the dryness of the mouth so frequent among drunkards.

The pancreas is, as the result of interstitial inflammation, the seat of similar changes. It is sometimes enlarged and softened, sometimes atrophied, shrivelled, or cirrhotic. In the latter condition its consistence is

¹ *Dictionnaire de Médecine*, art. "Alcoholism."

firm, its surface uneven, its color deep yellow, brown, or pale. Hyperplasia of the interacinous connective tissue, with subsequent contraction and atrophy and destruction of the glandular tissue, characterizes the more chronic forms of pancreatitis, and the organ is frequently the seat of scattered minute blood-extravasations. I have already alluded to the enlargement of the solitary glands which constitutes a feature of the condition of the large intestine. The solitary glands and Peyer's patches of the small intestine are rarely altered.

b. Disorders of the Liver.—Next in order to the stomach, the liver is more directly exposed to the action of alcohol than any other viscus. For this reason lesions of the liver are frequent and grave. It is worthy of note, however, that in a small proportion of cases of chronic alcoholism terminating fatally, with widespread evidences of the destructive action of alcohol upon the other organs of the body, the liver has been found, both in its macroscopic and microscopic appearances, wholly normal. Absorbed by the gastric vessels, alcohol passes directly, by way of the portal vein, into the parenchyma of the liver, there giving rise to various disturbances, the nature of which is determined by the tendencies of the individual on the one hand, and on the other hand by the character of the alcohol consumed. The danger of hepatic disease is in direct proportion to the amount and the concentration of the alcohol habitually taken. The steady drinkers of spirits of whatever kind, whether gin, brandy, whiskey, or rum, present the largest proportion of diseases of the liver. These affections are far less common among beer-drinkers, and infrequent among wine-drinkers in wine-growing countries. In this connection it is to be borne in mind that the presence of food in the stomach retards to some degree the absorption of the alcohol ingested, and to a certain extent constitutes a means of dilution.

Hepatic disorders due to alcohol may be arranged in two groups: first, congestion and inflammation; second, fatty infiltration or steatosis; and the inflammatory process may affect chiefly the interstitial connective tissue on the one hand, giving rise to sclerosis, or on the other the glandular substance, constituting a true parenchymatous inflammation.

Congestion.—Congestion of the liver is an early lesion. It is brought about by the direct irritant action of the alcohol itself in part, and in part by the extension of inflammation from the stomach by continuous mucous tracts. Its development is insidious. Anatomically, the condition is characterized by vascular dilatation, moderate tumefaction, slight increase in the consistence of the organ; the surface is of a deeper red than normal; on section the color is more intense and the oozing more abundant. At a later period we have, as the result of chronic congestion, the cyanotic liver; the color is brownish or violet, mottled, and on section the surface is granular and the lobules distinct. The organ may now be somewhat diminished in size, but it lacks the firmness of sclerosis and the hobnail appearance due to the contraction of the interlobular connective tissue in that condition.

The symptoms of congestion of the liver are the familiar symptoms of gastro-hepatic catarrh, varying from the transient disturbance known as biliousness to serious sickness, characterized by acute gastro-intestinal phenomena, with vomiting, headache, and other derangements of the nervous system—constipation, succeeded by diarrhœa and by more or less dis-

tinct jaundice. The graver forms of hepatic congestion are characterized by intense nausea, frequent vomiting, pain and soreness in the epigastrium and right hypogastrium, the physical signs of augmentation of the volume of the liver, and well-marked yellow discoloration of the conjunctivæ and skin. These attacks are usually afebrile: the pulse is slow; there is considerable nervous and mental depression, a tendency to vertigo, and occasional syncope. The urine is scanty and high-colored, and presents the reactions of bile-pigment. Muscular tremor, especially marked in the extremities and tongue, is often present, but is to be attributed rather to the direct action of alcohol upon the nervous system than to the condition of the liver.

Hepatitis.—There are two principal forms of inflammation of the liver induced by alcohol—parenchymatous hepatitis and interstitial hepatitis or sclerosis.

Several varieties of parenchymatous hepatitis have been described. The anatomical discrimination of these varieties is attended with less difficulty than their clinical diagnosis. One of the more serious is diffused parenchymatous hepatitis or acute yellow atrophy. Alcoholic excesses appear to constitute a predisposing influence to this grave disorder (Lentz). In several cases prolonged and repeated excesses have preceded its development. It is a true parenchymatous inflammation, in which the glandular elements of the organ undergo disintegration. The liver is diminished in volume in all its diameters. It is of a uniform yellow color; its tissue is soft and friable; upon section the hepatic cells are found to be replaced by a granular detritus mingled with globules of coloring matter and a greasy, grayish-yellow liquid exudation.

The symptoms of this affection are those of an acute parenchymatous hepatitis of the gravest kind. In the early stages there is intense jaundice, gastro-intestinal disturbance, and fever, followed by speedy evidences of profound toxæmia. The patient rapidly falls into the so-called typhoid state, with a tendency to coma. The prognosis is, in the greater number of cases, a fatal one. So close is the resemblance between acute yellow atrophy of the liver and the phenomena of acute phosphorus-poisoning that by many observers these two conditions are held to be identical.¹

There is little doubt that the view now generally held, that acute yellow atrophy is due to the action of some unknown toxic principle, is correct. Alcoholic excess must therefore be regarded merely in the light of a predisposing influence. Acute yellow atrophy of the liver is an exceedingly rare disease.

Suppurative Hepatitis.—Abscess of the liver is in temperate climates infrequent as the direct result of alcoholic excess. It is frequently ascribed, however, to improper alcoholic indulgence, especially when combined with the eating of large quantities of improper food, in tropical and subtropical climates. A form of hepatitis has been described by Leudet under the head of chronic interstitial hepatitis with atrophy. The symptoms are for the most part not very well marked, and consist chiefly in general malnutrition, which may in fact be dependent upon the associated gastric disturbance. Chronic jaundice is usually present.

Interstitial Hepatitis.—Cirrhosis of the liver is in a large proportion of cases directly attributable to alcoholic excess. In this view the greater

¹ Consult this *System of Medicine*, Vol. II., article "Acute Yellow Atrophy of the Liver."

number of observers coincide. But that alcohol is not the sole cause of chronic interstitial hepatitis has been abundantly established. As long ago as 1868, Anstie¹ wrote as follows: "Considering the enormous quantities of spirituous liquors which are drunk by many of the patients who apply for relief from the consequences of chronic alcoholism, it would be natural for the reader who holds the usual opinion as to the origin of cirrhosis of the liver to expect that serious symptoms produced by the latter disorder must often complicate cases of the former. The case is, however, far otherwise in my own experience. Of the immense number of patients in whom the nervous disorder has been clearly identified, I have only seen thirteen cases in which the symptoms of cirrhotic disease called for any special treatment, although a certain degree of cirrhosis was doubtless present in many of the others; and I cannot avoid the conclusion that some very powerful element over and above the influence of alcoholic excess is needed to produce the severe type of that disease." Formad² states as the result of his investigations as coroner's physician of the city of Philadelphia that cirrhosis of the liver is much less common in alcoholic subjects than has been generally thought. My own experience during eleven years as attending physician at the Philadelphia Hospital leads me to endorse this opinion.

The anatomical lesions of chronic interstitial hepatitis consist essentially in hyperplasia and hypertrophy of the connective tissue of the organ. The progress of the affection is insidious and gradual; some degree of enlargement, due in part to congestion and in part to interstitial exudation, is followed by gradual diminution, with retraction of the new connective tissue. When the connective-tissue new formation is excessive, and retraction fails to take place, the organ remains permanently enlarged (hypertrophic cirrhosis). During the first period the volume of the organ is increased, its consistence is more firm, and its surface is slightly granular. The second period is characterized by induration, with diminution of the volume of the organ and alteration of its form. The surface is uneven, deeply granular, and usually of a mottled yellow color. The tissue is firm, creaking under the knife. The connective tissue is enormously increased, the glandular elements being proportionately atrophied.

The contracting connective tissue exercises at the same time a compressing influence upon the hepatic cells and upon the vascular supply throughout the organ; the radicals of the portal vein and the branches of the hepatic artery are alike compressed, and in part obliterated. The same is true of the bile-ducts. The functional activity of the liver, at first diminished, is finally, to a considerable extent, arrested. In consequence of these physical alterations in the structure of the organ, the symptoms, which are at first insignificant, become progressively more grave, until at length they constitute complications of the most serious kind.

It can be no longer asserted that the interstitial hepatitis produced by alcohol presents specific characters. It nevertheless differs in many respects from that form due to valvular lesions of the heart, in which there are induration, usually augmentation in the volume of the organ,

¹ *A System of Medicine*, Reynolds, vol. ii, p. 74.

² *Proceedings of the Pathological Society of Philadelphia*, Dec., 1885.

and persistent congestion. Congestion, in truth, is the chief characteristic of the latter form, in which the surface is smooth and glistening, of a deep brown or violet hue, and on section yellowish or brown—a condition which has been well described under the term cyanotic liver.

Sclerotic changes due to alcohol usually affect the organ throughout. In this respect alcoholic cirrhosis differs from that form due to syphilis in which the lesions are irregularly distributed.

The functional disturbances due to cirrhosis are, in the beginning, obscure in themselves and masked by the concomitant gastric derangement. Later, ascites constitutes the chief as well as the most constant symptom. It is rarely altogether absent. Emaciation is also a prominent symptom. No affection, not even diabetes or phthisis, produces loss of flesh so rapid, so marked, and so significant as cirrhosis of the liver in chronic alcoholism. Not only do the adipose tissues waste, but the muscles themselves undergo rapid atrophy. This fact is not surprising when we consider that the lesions of the liver give rise to grave interference with every function of that organ. In addition to the more common gastric symptoms, there is constipation, not rarely alternating, without assignable cause, with serous and sometimes bloody diarrhœa. Epigastric distress, epistaxis, and hemorrhages from other mucous surfaces are common, and are due in part to the disturbance of the general circulation, and in part to alterations in the character of the blood itself. The physical signs indicate in the early stages increase, and afterward diminution, in the volume of the liver. Enlargement of the superficial abdominal veins is a characteristic sign. Cirrhosis of the liver is a grave affection, the course of which, at first slow, afterward more rapid, almost invariably leads to a fatal termination.

Fatty Degeneration of the Liver.—Steatosis of the liver is of extremely common occurrence in the advanced stages of alcoholism. The anatomical changes consist in accumulation of fat-globules in the liver-cells. French writers distinguish two varieties of hepatic steatosis: first, that in which the cellular elements undergo no change beyond that of an accumulation of fat-globules within their substance; and second, that in which the liver-cells undergo an actual disintegration, in the course of which fat-granules are formed, and which is, as a matter of fact, a true fatty degeneration. The first of these conditions is not incompatible with the functional integrity of the organ, and is in many instances unattended by symptoms, being discovered only upon examination after death. Its occurrence is to be explained by the imperfect oxidation of waste products due to the constant presence of alcohol in the blood, and by the habitual excess of fat in the latter fluid. When fatty infiltration is of moderate amount there are no changes in the volume or the contour of the organ, and the condition is recognized only on microscopical examination. At a later stage the organ becomes enlarged, particularly in its antero-posterior diameter. The surface is now smooth and glistening, its color yellow or reddish-yellow; upon section it is anæmic, of a yellowish color, with patches of a reddish hue, and its consistence is diminished. The indentation caused by pressure of the finger persists. Under the microscope the hepatic cells are enlarged, rounded, packed with fat-globules of varying size. In some of the cells these globules coalesce and form more or less extensive drops of fat. The bile which is

secreted in this condition presents in most instances the normal characteristics.

Disorders of digestion do not occur in consequence of the fatty change in the liver until the lesion has reached an advanced stage; nevertheless, they constitute the earliest symptoms of this condition. Imperfect digestion, accompanied with flatulence, distension of the belly, epigastric tenderness, with light-colored stools, and constipation alternating with diarrhoea, are common symptoms. There is no pain properly referable to the region of the liver. Whilst icterus does not occur, there is, nevertheless, a peculiar earthy pallor of the complexion and persistent greasiness of the skin—conditions, however, which are not in themselves sufficiently marked to possess, in the absence of other signs, clinical value.

The second form of fatty degeneration, in which the liver-cells undergo actual and destructive metamorphosis, accompanied by the production of fat, is of a much more serious character. It appears to constitute the stadium ultimum of various forms of interstitial hepatitis, and is manifested by symptoms of the gravest character, in many particulars much like those met with in acute yellow atrophy—namely, visceral congestions, hemorrhages from mucous surfaces, serous effusions, profound and rapidly developing anæmia, nervous depression, and coma.

Biliary Catarrh.—The biliary ducts are usually the seat of catarrhal inflammation, due less perhaps to the direct irritant action of the alcohol than to the extension of the inflammation of the gastric mucous membrane in the form of gastro-duodenal catarrh. Gall-stones are not common in alcoholism.

The spleen is, as a rule, enlarged, soft, and friable; occasionally it is small and shrivelled. No characteristic changes in its contour and structure have been recorded.

The great omentum and mesentery are loaded with fat, very often to an extreme degree. This condition is more marked in the chronic alcoholism of beer-drinkers than in that of spirit-drinkers. Not infrequently there are found evidences of chronic peritonitis, which has been attributed by Lancereaux, in the absence of other assignable cause, to the effect of alcohol itself. The symptoms of this condition are usually obscure, consisting of diffused dull pain, augmented upon pressure, diarrhoea, digestive troubles, and abdominal distension, sometimes voluminous, often irregular.

c. Disorders of the Respiratory System.—**The Larynx.**—Catarrhal inflammation of the mucous membrane of the air-passages is common in drunkards. Some degree of subacute or chronic laryngitis is an early symptom of chronic alcoholism. It may result from repeated attacks of acute alcoholism, or it may be among the first signs of excesses that are continuous, without at any one time being extreme. In the production of this local trouble the direct action of alcohol is reinforced by the foul and smoke-laden air of the apartments in which tipplers spend much of their time and by heedless exposure to the vicissitudes of the weather. The anatomical changes are those of chronic laryngitis in general, hyperæmia of the mucous membrane with minute ecchymoses, local destruction of epithelium with superficial ulcerations or granulating surfaces. The mucus is often thick, opaque, and adherent.

These lesions are accompanied by more or less decided impairment of function. The voice is hoarse and husky; there is fatiguing laryngeal cough, usually harsh and grating in character, and attended by scanty muco-purulent expectoration. This cough is often paroxysmal; especially is it apt to be so on rising, and it then provokes the vomiting previously described.

The Bronchi.—After a time similar anatomical changes are brought to pass in the bronchial tubes. Subacute bronchitis is little by little transformed into the chronic form, characterized by hyperæmia and thickening of the mucous membrane, extending to the finer twigs, with submucous infiltration and implication of the connective-tissue framework of the lung. The exudation, tough and adherent or fluid and copious, occasions more or less frequent cough, and interferes with the function of respiration. Hence it is common to encounter in the subjects of chronic alcoholism bronchiectasis, pseudo-hypertrophic emphysema, easily excited or permanent dyspnoea, asthmatic seizures, and some degree of cyanosis. These local affections, interfering with the circulation of the blood and its proper aëration, react unfavorably upon the nutrition of the organism at large, and largely contribute to the production of the ultimate dyscrasia.

The Lungs.—Pulmonary congestion and œdema are of common occurrence. Favored by the action of alcohol upon the vaso-motor system, they are readily excited by the careless habits and frequent exposures of the subject. The lesions occupy by preference the lower and posterior parts of the lungs, and consist in relaxation of the parenchyma, with vascular dilatation and serous infiltration. The vesicles are capable of distension, but contain little air. The tissue is friable, deep-red or brownish in color, and floats upon water. The symptoms of this condition are sometimes obscure: usually they consist in a sensation of constriction of the thorax, more or less dyspnoea, mucous expectoration, sometimes streaked with blood, and lividity of the countenance and finger-tips. The chief physical signs are impaired percussion resonance and mucous, subcrepitant, and occasionally a few scattered crepitant râles.

Pulmonary Apoplexy.—When the congestion is extreme, blood may escape into the parenchyma of the lung with laceration of its substance. This lesion is more frequent in intense acute alcoholism than in the chronic form.

Pneumonia.—Habitual alcohol-drinkers are far more liable to pneumonia than others. It has even been asserted that alcohol is of itself capable of acting as an efficient exciting cause. Whilst it is indisputable that the action of this agent upon the pulmonary blood-vessels and in favoring pulmonary congestion constitutes a powerful predisposing influence, it cannot be admitted, regard being had to the fact that it is largely eliminated by the lungs, that alcohol can, in the absence of a specific cause, ever produce a specific acute febrile disease, such as croupous pneumonia. The pneumonia of alcoholic subjects, like that of aged persons and that occurring in the convalescence from acute diseases, is apt to be latent. The exudation is often of limited extent; the symptoms are insidious, and the striking clinical features of the ordinary frank form of the affection are not rarely absent altogether. It is no infrequent occurrence that pneumonia is overlooked in the delirium tremens which it has induced.

The anatomical changes are those of the ordinary form. The prognosis

is always grave. When recovery occurs resolution is often tedious and prolonged.

Catarrhal pneumonia is also common. It is marked by its usual phenomena.

The most striking fact in the pneumonia of alcoholic individuals is the contrast between the local and the constitutional symptoms. The former are in the greater number of the cases insignificant and easily overlooked. Even the physical signs, when sought for, are often obscure and indeterminate: relative dulness, enfeebled or absent vesicular murmur, faint scattered crepitation masked by mucous râles, and a bronchial respiratory sound scarcely appreciable, are all that can be detected upon physical examination. In strong contrast to this almost negative picture is that of the constitutional disturbance, which is commonly of the gravest kind. The prostration is extreme; there is delirium with tremor, restlessness, sleeplessness, mental agitation, profuse sweating, feeble action of the heart, gastro-intestinal irritation, with vomiting and often complete inability to retain food. The temperature-curve lacks the characters of pneumonia of the ordinary form. Not seldom is febrile movement absent altogether.

The view that alcohol, independently of and in the absence of other lesions, occasionally produces changes in the lungs analogous to the chronic interstitial inflammatory processes of cirrhosis of the liver—*i. e.* fibroid phthisis—is not borne out by clinical or pathological investigation, and appears to be wholly without foundation in fact.

Pulmonary Phthisis.—The question whether or not chronic alcoholism exerts any influence in the production and evolution of pulmonary phthisis has been the subject of no little fruitless controversy. There are medical men of experience who do not hesitate to affirm that the abundant use of alcohol constitutes in certain cases an actual prophylaxis, while there are others who insist with equal positiveness that alcoholic excesses favor the development of this affection. Whatever may be the influence of alcohol in depressing the forces of the body and in the production of serious lesions of pulmonary structures, and thus predisposing the subject to phthisis, it can be asserted with confidence that it does not directly cause any form of phthisis whatever. The alcoholic phthisis of Lancereaux, Richardson, Drysdale, and others cannot be now regarded as a distinct, independent affection. The process of exclusion by which alcohol was made to seem the real cause of the disease in 36 of 2000 of the cases examined by Richardson was not sufficiently rigid to meet the requirements of our present knowledge. There is reason to believe that by its favorable influence upon the appetite and digestion, its power to reduce temperature, its retarding influence upon tissue-waste, alcohol in moderate quantities is of great use in the management of this affection. That phthisical subjects occasionally seem to derive benefit from, and to lengthen their lives by, excesses in alcohol is capable of explanation—first, by the fact that an extraordinary tolerance for alcohol is natural to or acquired by certain individuals; and, second, by the favorable influence of alcohol upon ulcerative and suppurative processes, and in determining connective-tissue new formation—a process by which certain inflammatory products, including tubercle, are capable of being rendered inert. The foregoing remarks are applicable to all forms of pulmonary phthisis.

The Pleuræ.—The pleura is sometimes the seat of patches of fibrinous exudation of varying extent and thickness, which are, according to Lentz, the expression of the formative action which constitutes one of the modalities of alcoholism, and which are of the same nature as the fibrinous exudations which occur in the peritoneum and the dura mater. These false membranes cause pleural adhesions, and occasionally contain within their meshes a turbid serous fluid.

d. Disorders of the Circulatory System.—The Heart.—This organ is usually implicated to a greater or less extent in the course of chronic alcoholism. Lesions of the muscular substance are more common than those of the valvular apparatus.

Hypertrophy is common. It affects usually both sides of the heart—the left, however, more than the right—and is associated with some degree of dilatation. The part played by alcohol in the production of cardiac hypertrophy is a dual one: first, that of constantly-repeated direct stimulation of the heart; second, that of the indirect stimulation to over-action caused by the necessity to overcome the obstacles which the lesions of the viscera interpose to the circulation of the blood in the later periods of the disease. Nor are the lesions of the blood-vessels themselves, hereafter to be described, without influence in inducing hypertrophy. Bollinger and Schmidbauer have shown that the habitual consumption of beer in excessive quantities leads to cardiac hypertrophy of characteristic form. Both sides of the heart participate in the over-growth: there is enormous increase in the volume of the primitive muscular elements, with enlargement of the nuclei. Whether or not actual numerical increase in the muscular fibres takes place cannot be determined. This form of enlargement of the heart occurs in the absence of lesions of the valves, disturbances of the pulmonary circulation, arterial sclerosis, atheroma, or granular kidneys. Some few of these cases of so-called idiopathic hypertrophy are perhaps due to prolonged excessive bodily effort and bodily strain. But the greater number are only to be explained by habitual excesses in beer-drinking, as shown by carefully worked-out personal histories of the patients. Neither fatty degeneration nor myocarditis enters into the pathological process under consideration. The hypertrophy is due to the direct action of the alcohol consumed, to the enormous amount of fluid introduced into the body, and to the easily-assimilated nutritive constituents of the beer itself. Furthermore, such habits are often associated with great bodily activity and a relatively luxurious manner of life. The greater number of alcoholic subjects who suffer from this form of hypertrophy perish after brief illness with symptoms of heart-failure. At the necropsy are discovered moderate dropsy, congestion and brown induration of the lungs, congestion of the liver, spleen, kidneys, and other organs, bronchitis and moderate serous effusions or general anasarca. Death is probably due to paralysis of the cardiac nerves and ganglia. This form of hypertrophy is of course much more common among men than among women. It is much less common in this country than in Germany, but is occasionally met with among brewers' employés.

Fibroid Degeneration.—This condition has been ascribed to a number of causes, among which long-continued excess in alcohol is unquestionably an important one. Bramwell holds the opinion that in a certain prob-

portion of cases of this description, in which fibroid degeneration of the heart is connected with similar changes in the kidneys (sclerosis), the lesions of both organs are due to alcoholism. Alcoholic fibrosis differs in no respect from that due to other causes. The condition may escape recognition by the unaided eye if it be disseminated throughout the muscle and the change consist in thickening of the perimysia around undivided fibres. The heart is larger than normal, perhaps a little paler, and its consistency a little more firm. When, as is more commonly the case, the fibroid change is localized, and masses of new tissue are developed in and around the muscular fibres, the heart assumes a flecked or streaked appearance, due to the contrast between the yellowish-white fibroid tissue and the brownish-red muscular structure. The microscope shows excessive development of fibrous tissue, with atrophy of muscular fibres. The effect is to weaken the force of the heart's action, and to weaken the walls of the cavities at the affected parts in such a manner as to cause local bulgings or cardiac aneurisms.

The symptoms and physical signs of fibroid degeneration of the heart are very obscure and indefinite, and the diagnosis is always attended with difficulty, and in many cases is impossible. Jubel-Renoy, however, regards the diagnosis as having already attained some clinical exactitude, and regards as important the association of the following diagnostic data: first, feebleness of the systole and the pulse, with augmentation of the frequency without irregularity; second, moderate enlargement, varying within considerable limits; and third, absence of murmurs in the greater number of the cases. Death is apt to occur suddenly. Welch, upon investigation of the clinical histories of cases in which fibroid degeneration of the heart was found after death, concluded that they might be clinically grouped as follows: first, cases in which there is no symptom of heart disease; second, cases of sudden death without previous heart symptoms; third, sudden death preceded by one or more attacks of angina pectoris; fourth, after cardiac insufficiency of a few days' standing; and fifth, in cases of old heart disease.

Fatty Heart.—Under the term fatty heart two distinct pathological conditions are comprised. Of these the first is fatty infiltration, which consists in an excessive development of the normal subpericardial fat, with a deposition of fat-cells in considerable number between the muscular fibres of the myocardium. This condition occurs chiefly in individuals suffering from general obesity, and is particularly apt to occur in alcoholic obesity. Large masses of fat fill the grooves and furrows of the organ, the surface of which is covered with a thick layer of yellowish fat. The right heart is first and most affected, but in advanced cases the whole heart may be encased in a thick fatty layer. When the fat-cells infiltrate the intermuscular spaces, they exert pressure which may produce atrophy and degeneration of the muscular elements. This condition may exist to a certain extent without symptoms, but it is, however, apt to be manifested by a certain amount of cardiac dyspnoea and inability to endure excessive strain or acute illness. In cases in which the fatty infiltration attains a high grade, inducing by mechanical pressure degenerative changes in the muscular substance of the heart, there are signs of embarrassment of the circulation. The precise diagnosis is usually difficult, often impossible.

The second form of fatty heart is known as fatty degeneration, and consists in changes in the muscular fibres by which the albuminoid constituents are broken up and replaced by microscopic particles of fat. After a time the transverse striæ disappear, and the functional activity of those muscular fibres which are affected is completely lost. All conditions which interfere with the supply of oxygen to the muscular tissue or which seriously derange its nutrition are capable of producing fatty degeneration. Among these are alcoholic excesses. The color of the heart is paler than normal, usually fawn or pale buff. It has been described as the faded-leaf color. The consistence is softer than normal, the wall of the heart in many instances being readily broken down by the pressure of the finger. The left ventricle is the part most likely to be affected, the papillary muscles being often profoundly altered. Next in order the right ventricle is involved, then the left auricle, and finally the right auricle. When this form of degeneration is due to disease of the coronary arteries, the lesion is usually localized, sometimes limited to the distribution of the branch of the artery which is affected.

Upon microscopical examination the affected muscular fibres are found to contain minute molecules of fat, often of a uniform size, sometimes arranged in rows, but commonly distributed irregularly throughout the substance of the fibre. The transverse striæ are indistinct, and sometimes wholly absent. The functional activity of the affected fibres is seriously interfered with or wholly lost, and as a result the force of the circulation is greatly weakened. These two forms of fatty change are occasionally associated. Among the more common symptoms are shortness of breath upon exertion, with dry hacking cough. In advanced cases the dyspnoea may become constant. The fatal issue is sometimes preceded by the Cheyne-Stokes respiration. Other symptoms are due to cerebral anæmia. The memory is impaired, the patient becomes wayward and irritable, and is apt to become faint upon suddenly changing from the recumbent to the erect posture, and in most instances is incapable of concentrated mental effort or active bodily exertion.

The Blood-vessels.—Capillary dilatation is one of the earliest and most persistent effects of alcohol. The visceral congestions which constitute so important a factor in the pathology of alcoholism are in part the result of the paralyzing action of alcohol on the vaso-motor system, and in part of the degenerative changes in the unstriated muscular fibres of the arterial walls.

Atheroma.—Alcoholic excesses play an important part in the etiology of atheromatous degeneration of the arterial walls, not so much by the direct action of the alcohol itself, as by its indirect action in increasing the tension in the main trunks, and in leading to an irregular life in which excitement, sudden and severe exertion, exposure to cold, and depressing influences of all kinds play a part.

Valvular lesions of the heart do not occur as a direct result of the action of alcohol.

e. Disorders of the Genito-urinary Apparatus.—The Kidneys.—Alcohol, as has been shown above, is a diuretic. In large doses it produces renal congestion. Ollivier¹ observed acute transient albuminuria resulting from the influence of excessive doses of alcohol.

¹ *Essai sur les Albuminuries produites par l'Elimination des Substances toxiques*, Paris, 1863.

Much difference of opinion exists as to the part played by alcohol in the causation of the various forms of Bright's disease. It was at one time thought that a large proportion of the cases were due to the abuse of this substance. Bright held this view, and Christison attributed from three-fourths to four-fifths of all cases of granular degeneration of the kidneys to the abuse of spirits. The latter considered that not alone in notorious drunkards was this result likely to occur, but even in those accustomed to the moderate daily consumption of spirits with only occasional excesses. This opinion for a long time largely prevailed among English writers. Of late years, however, in consequence partly of the teachings of Anstie and Dickinson, partly of more precise methods of reasoning, the direct causative relation between chronic alcoholism and disease of the kidneys has come to be questioned. Nevertheless, many teachers of authority adhere to the former view. It is, however, more than probable that the action of alcohol is not of itself capable of producing these effects in the absence of other causes, among which are insufficient or improper diet, irregular living, damp dwelling-places, occupations necessitating great or prolonged exposure to cold and wet or such exposure from accidental causes—circumstances to which those who, especially among the poorer classes, are addicted to drink are peculiarly liable. Nor must we overlook the influence of exposure to paludal poison, of lead, and of heredity in the causation of diseases of the kidneys. While alcohol cannot be regarded as the direct exciting cause of acute or chronic nephritis, chronic alcoholism acts as an influence predisposing to the development of these affections in persons otherwise liable to them.

Congestion of the Kidneys.—The general action of alcohol in inducing visceral hyperæmia is aided by its special diuretic action in causing chronic congestion (cyanotic kidney). The kidney is of a dark violet-red hue, slightly enlarged, especially in its transverse diameter, of a consistence firmer than normal, and bleeds freely upon section.

Acute parenchymatous nephritis is of rare occurrence in chronic alcoholism. Of chronic parenchymatous nephritis Bartels¹ writes: "I may say that alcoholic excesses, to which the disease is by many attributed, cannot be charged with being the cause of it. None of the cases treated by me occurred in drunkards, and in no instance have I encountered the large white kidney at the autopsies of notorious drinkers, of which I have made a not inconsiderable number during my many years' active hospital service." The same author in discussing the etiology of chronic interstitial nephritis (contracted kidney) enters a protest against the view which is widespread in England that the abuse of spirituous liquors favors the development of the genuine contracted kidney. He says: "In the first place, among all the patients whom I have treated, three only were brandy-drinkers to any notorious excess, while by far the greater number who were affected with this complaint had lived remarkably abstemious lives. In the second place, throughout my twenty-five years of active service as a hospital physician I have had the most abundant opportunity of watching the consequences of intemperance, both at the bedside and upon the post-mortem table; yet these three cases have hitherto been the only ones in which I have found atrophied

¹ *Ziemssen's Cyclopædia of Medicine.*

kidneys in the bodies of habitual drunkards." Baer also testifies to the infrequency of contracted kidneys among drunkards.

Fürstner detected by very exact testing a trace of albumen in the urine of almost all cases of delirium tremens examined. Its presence was, however, transient, and appeared to be not associated with structural changes in the kidneys.¹

Fatty infiltration and fatty degeneration of the kidneys occur in chronic alcoholism, the former as part of the general fat accumulation, the latter as a result of the general nutritive disturbances.

Amyloid degeneration is rare, and can in no case be ascribed to the direct action of alcohol.

Griesinger saw excessive diabetes insipidus follow a prolonged and severe attack of acute alcoholism in a man twenty-eight years old, and terminate fatally in the course of four months. Ebstein attributes the polyuria of acute alcoholism to lesions of the brain.

Glycosuria is rare among drunkards.

The Bladder.—Catarrh of the bladder is not rare in chronic alcoholism, especially in that form originating from excesses in malt liquors. This condition, however, scarcely occurs with sufficient frequency to be regarded as in any sense a symptom of alcoholism.

The Genital Organs.—The subjects of alcoholism are especially prone to sexual disorders of all kinds—a fact to be explained by the influence of alcohol on the imagination, and especially upon the sexual appetite, its debasing effect on the moral sense and upon the judgment, and the indifference to the consequences of exposure which it begets. In the later stages of chronic alcoholism sexual power is apt to be greatly enfeebled or wholly lost. This condition, which is usually attended also by loss of sexual desire, is to be attributed to the action of alcohol upon the nervous system rather than upon the sexual organs themselves. It has nevertheless been established that long-continued alcoholic excesses are apt to be followed by atrophy of the testicles. Lancereaux has described a condition of these organs resembling in all respects senile atrophy. On the other hand, Huss attributed the impotence of alcoholic subjects to loss of nervous tone. In the female, alcoholism produces disturbances of menstruation and premature menopause. Alcoholic excesses are said also to produce a liability to abortion, and Lancereaux has observed atrophy of the ovaries in alcoholic subjects.

2. *Disorders of Special Structures.*—*a.* Disorders of the Locomotive Apparatus.—The muscles at large, like the heart, are liable to fatty infiltration and degeneration. Fatty infiltration, frequent at some period in the course of the affection, is apt to be widespread. The muscles are paler than normal, softer in consistence, and streaked with fat. True fatty degeneration is less frequent, and apt to be localized. Here the muscular fibres lose their striation, and present within the myolemma minute fatty deposits in the form of granules. This change is accompanied by atrophy. The symptoms consist in feebleness and difficulty in movement and in locomotion.

Changes in the bones, notably enlargement of and increase in the contents of the medullary canal in the long bones, and arthropathies of various kinds, have been observed in alcoholic subjects.

¹ *Berliner klin. Wochenschrift*, 1876, No. 28.

b. Disorders of the Skin.—Alcohol is a sudorific, and is largely eliminated by the skin. This effect is purely physiological; therefore the moderate and occasional use of alcohol exerts an influence rather favorable than otherwise upon the tegumentary structures, but in repeated excesses it gives rise to more or less cutaneous irritation. The skin, partly for this reason, and partly because it shares in the general disturbance of nutrition, becomes dry, harsh, and scaly; after a time the face, and especially the nose and neighboring parts, assumes in many instances a violaceous hue, the minute superficial cutaneous veins are enlarged, and acne is common. The resulting appearance is almost characteristic of the habits of the individual. Alcoholic subjects frequently suffer from pruritis, urticaria, and eczema. In certain cases the skin, instead of being dry and harsh, is soft and unctuous, and in others, especially in the more advanced cases, it becomes slightly yellow or earthy in hue. Owing in part to changes in the nutrition, and in part to vascular dilatation, the skin of the extremities is not rarely mottled and cyanotic. In certain forms of alcoholism of the nervous system, and particularly in alcoholic paralysis, in which we have to do with multiple peripheral neuritis, the skin of the affected parts, especially that overlying the atrophied muscles, becomes, in consequence of trophic changes, dusky in color and hard, smooth, and glossy. It has been stated that chronic alcoholism is a cause of pellagra, and numerous observations have been advanced in support of this view (Hardy). The excessive rarity of this condition in countries in which the abuse of alcohol is most common renders it probable that the occasional association of these affections is accidental rather than causal. Chronic alcoholism predisposes to gangrene of the skin and to bed-sores; slight wounds readily inflame and are slow to heal; alcoholic subjects are especially predisposed to erysipelas, while the enfeeblement of the circulation and the lowered tone in the later stages of chronic alcoholism often result in œdema of the inferior extremities.

3. General Disorders.—In addition to the various local disorders thus far described, the prolonged excessive indulgence in alcohol leads to profound disturbances of the processes of nutrition, which are manifested in alterations in the blood, in excessive accumulation of fat, and in a well-marked cachexia.

a. The Blood.—The alterations in the blood, although sufficiently manifest in disorders of nutrition, have not yet been studied with satisfactory results. In chronic alcoholism the proportion of water is increased, while that of fibrin is diminished. After death the blood remains fluid. The red globules are diminished in number. The blood also contains free fat, to which it owes its pale, opalescent, and sometimes almost milky hue. The presence of fat has been demonstrated after the injection of alcohol into the veins of animals.

b. Obesity.—Fat-infiltration and fat-accumulation must be regarded as among the most characteristic disturbances produced by alcohol. Fat is abundantly stored up in the subcutaneous tissues. The anterior abdominal wall is especially liable to its accumulation. The heart, kidneys, omentum, and mesenteries are also not infrequently the seat of abnormally large accumulations of fat. Fat also collects in the muscles and in the intermuscular planes, but to a less extent. Obesity is not, however, so frequent in the advanced stages of alcoholism as it is while the subject

has not yet lost the appearance of health, and in a large proportion of the individuals it does not manifest itself at all. It appears to depend largely upon the character of the drink, and is especially frequent among those addicted to excesses in beer. It is less common among wine-drinkers, and relatively infrequent and of moderate degree in those who confine themselves to spirits. A sedentary life, and perhaps also an hereditary tendency, exerts an important influence upon the development of obesity in alcoholism.

c. *Alcoholic Cachexia*.—The action of alcohol in excessive amounts upon the nutrition of the body at large, and in particular upon the nutrition of the nervous system, is radically unfavorable. This unfavorable influence manifests itself from the beginning, while the subject yet presents the appearance of health, and long before the occurrence of either the symptoms or physical signs of organic disease. The powers of resistance to unfavorable influences of all kinds are diminished; the ability to endure hardships, privations, and fatigue is lessened; sickness and injuries are badly borne; complications are frequent and grave; and convalescence is apt to be tardy and insecure. It is among the more striking peculiarities of the alcoholic subject that blood-losses are badly borne and slowly repaired. It is this want of tone, often latent for a long time under ordinary circumstances, which unfits those addicted to alcohol for Arctic and exploring expeditions and for military and scientific enterprises involving prolonged hardship and exposure. In the course of time disorders of the digestion, of hæmatosis, of circulation, increase the difficulty and render it more apparent. The fat now rapidly diminishes; anæmia develops; the complexion becomes dull, earthy, or slightly jaundiced, the tissues flabby. Then follow diarrhoea, hemorrhages from mucous surfaces, serous effusions, visceral congestions of high degree, hypostasis, œdema, and progressive deterioration of all the powers alike of the body and the mind until the dyscrasia is complete.

The subjects of chronic alcoholism are especially prone to affections of the respiratory tract and to the infectious diseases. They furnish, as a rule, the earliest victims in epidemics. They not rarely die of pneumonia. They develop troublesome delirium in simple maladies, and in all acute affections the prognosis is unfavorable as compared with that in persons of sober habits. As Clouston well says, "The whole organism suffers sanative and mental lowering, alteration of functions and of energizing."

B. *DERANGEMENTS OF THE NERVOUS SYSTEM: CEREBRO-SPINAL DISORDERS*.—The disorders of the central nervous system in chronic alcoholism are even more numerous and more important than those already described. Many transient and permanent disturbances of function occur without anatomical lesions recognizable by existing methods of examination; many others are associated with readily-discoverable changes of structure. These changes are encountered in the blood-vessels, the meninges, the substance of the cerebro-spinal axis, and in the peripheral nerves. Much as they differ in appearance and in their clinical manifestations, they may all be referred to three processes: (a) congestion and inflammation; (b) sclerosis; and (c) stentosis.

1. *Cerebral Disorders*.—The *Cranium*.—The bones of the skull are often thicker and more dense than normal. This change implicates the

diploë and the outer and inner tables. The last is then deeply channelled for the blood-vessels and deeply indented for the Pacchionian bodies, which are commonly hypertrophied.

The Vessels.—Disturbances of the cerebral circulation are among the earliest and most important symptoms. Due primarily to the increased action of the heart and vaso-motor dilatation of the blood-vessels excited by repeated large amounts of alcohol, and secondarily to permanent enlargement of the vessels in consequence of fatty or atheromatous degeneration of their walls, some degree of active or passive congestion is almost always present. It is probable also that in consequence of irregular and complex disturbances of the circulation secondary localized ischæmia occurs. Lentz states that anæmia is more common in the cerebral substance than in the membranes.

The capillaries are usually much altered—sometimes uniformly dilated to a considerable extent, sometimes forming capillary aneurisms. They are more sinuous than normal, their walls show evidences of fatty degeneration, and they sometimes contain minute thrombi. Extravasated blood, in the form of circumscribed collections, of diffuse layers, or finally of capillary hemorrhages, also occurs. These collections are sometimes free, sometimes encysted.

The Meninges.—The dura mater is congested; occasionally it shows more or less extensive areas of inflammation with exudation of lymph. Purulent exudation in the absence of traumatism is rare. The lymph may be deposited in the form of patches of varying extent, or it may form more or less extensive false membranes. These accumulations are of variable, often considerable, thickness, and constitute the condition described as pachymeningitis hæmorrhagica interna, or, from the large amount of blood which they contain, hæmatoma of the cerebral meninges. They occupy the convexity of the brain, and are developed upon the inner surface of the dura; they are usually nearly symmetrical in outline, but of different thickness upon the two sides. They consist of superimposed layers of lymph, between which, or within the substance of which, are more or less extensive blood-extravasations, either fluid, coagulated, or undergoing resorption. More frequently the exudation consists of mere shreds of lymph within the cavity of the arachnoid.

The arachnoid is almost invariably altered. Upon the convex surface of the hemispheres, especially along the median fissure, it is thickened and opaque. This condition may be uniform or distributed in patches, and is apt to follow the line of the blood-vessels.

The pia mater is congested, often œdematous, not rarely the seat of blood-effusions of greater or less extent.

The cerebro-spinal fluid is usually more abundant than normal, of a deeper color, cloudy, sometimes tinged with the coloring matter of the blood.

The Brain.—The intimate lesions of the substance of the brain are not yet known. The volume of the encephalon, as a rule, undergoes no change. Occasionally it appears to be swollen, and protrudes with some degree of force through the incision first made in the membranes. More commonly, the brain is throughout or in certain parts atrophied or shrivelled, its convolutions flattened, its surface retracted. This is sometimes the result of the pressure of collections of hemorrhagic or inflammatory products.

The consistence of the cerebral mass is sometimes increased ; it becomes harder, more resistant to pressure, and preserves its form when removed from the cranium better than the normal brain. This condition may be present throughout the brain or it may be localized. In the latter case it is usually due to patches of sclerosis. Softening in more or less extensive areas may occur in the advanced stages of the more severe forms of chronic alcoholism. It is found chiefly in the gray substance, where the vessels are more numerous, especially in the cortex and central ganglia. In this as in other affections cerebral softening is the result of obstruction of the circulation in consequence of atheroma, thrombosis, or other change in the arteries. It varies from simple diminution in consistency to diffidence.

The nervous substance of the brain doubtless undergoes changes proportionate to the degree and duration of its exposure to an alcohol-charged blood. What these changes are has not yet been fully determined. The nerve-cells of the cortex have been found rounded and contracted, so that instead of being surrounded by a small lymph-space they seem to be lying in large cavities, and so granular that the nucleus can hardly be made out. Slight increase in the number of the small round cells in the cortex and in the adjoining parts of the white matter has also been observed (Hun). These changes are not, however, constant. Not only has the microscopical morbid anatomy of the lesions of nerve-substance peculiar to chronic alcoholism not yet been worked out, but even macroscopic changes adequate to account for symptoms that were during life serious, persistent, and apparently referable to well-defined lesions, are sometimes absent altogether.

It is important to distinguish the disorders due to the direct action of alcohol, which are often functional or dependent upon lesions too subtle for recognition, from those which are secondary and dependent for the most part upon coarser changes of structure.

In consequence of hyperæmia of the brain and its membranes there not infrequently occur a sense of confusion or dulness, increasing to headache, which may become almost unbearable, mental disturbances of the most varied character, disorders of movement and sensation, and disorders of the special senses.

Cerebral hemorrhage, to which the subjects of chronic alcoholism are, in consequence of the vascular lesions already described, peculiarly prone, manifests itself by the usual primary and secondary phenomena. Meningeal hemorrhage, save in the form of hæmatoma, is rare except in the advanced stages of paretic dementia.

The blood in alcoholic dyscrasia undergoes changes which favor its transudation through the walls of the vessels ; hence a tendency to œdema and to accumulations in serous sacs. This tendency implicates the structures of the nervous system in common with the organism at large. The ventricles of the brain become distended with fluid, and the brain-substance itself and the meninges not rarely become œdematous in the last stage of chronic alcoholism, in consequence of grave disturbances of the circulation or as complications of affections of the lungs, heart, or kidneys. These conditions are attended by mental obscuration, somnolence alternating with sleeplessness, delirium, maniacal paroxysms, impairment

of muscular power, of general and special sensibility, impaired reflexes, inability to speak, deepening stupor, and death.

2. *Spinal Disorders*.—Lesions of the spinal cord or its membranes have been rarely discovered. When present they have been invariably associated with similar or corresponding lesions of the brain or its envelopes. Leyden¹ states that not only do the cerebral meninges present inflammatory changes in chronic alcoholism, but the meninges of the cord are sometimes found in an analogous condition; that pachymeningitis hæmorrhagica interna spinalis has also been observed, as well as other forms of spinal meningitis, with thickening and discoloration of the pia and dura; and that œdema of the pia has been especially noted. While anatomical lesions of the cord are less frequent than lesions of the brain, nutritive and functional disturbances, as manifested in the general symptomatology, are quite as common in one as in the other.

3. *Disorders of the Peripheral Nerves*.—Magnus Huss found no change in the peripheral nerves in five cases in which they were carefully examined. Lancereaux discovered degenerative changes in the peripheral filaments in alcoholic paralysis. Leudet found hypertrophy of the neurilemma and alterations in the cubital nerve in an individual suffering from chronic alcoholism in whom this nerve was paralyzed. Dejerine² observed in two fatal cases of alcoholic paralysis neuritis of peripheral nerves with integrity of the nerve-roots, the spinal ganglia, and the cord. In one of Dreschfeld's cases of alcoholic paralysis,³ in which the cord was found perfectly normal, the "sciatic appeared thin and grayish, and was surrounded by a great deal of adipose tissue. Vertical sections showed, when treated with perosmic acid and stained afterward with picro-carmin, a moniliform appearance of the nerve-tubes, due to breaking up of the myelin; the nuclei were increased, and there was also some interstitial cell-infiltration. Transverse sections showed in some few places an increase in the diameter of the axis-cylinder, and again the interstitial infiltration."

Disorders of General Sensibility.—Disorders of general sensibility are among the earliest of the nervous phenomena of chronic alcoholism. They occur in the following order: hyperæsthesia, dysæsthesia, and anæsthesia. Disturbances of sensibility manifest themselves, quite independently of hallucinations, as sensations of malaise, of discomfort, of chilliness, of cramps, or of abnormal warmth or cold. Sometimes they amount merely to momentary discomfort, at other times to extreme pain. They are usually limited, often to the feet and legs, sometimes to the hands and arms; again, they are experienced in the trunk, and especially in the back. They are most common during the evening; less frequently they are induced by the warmth of the bed; and, again, they are experienced on rising. They are apt to be associated with occipital or frontal headache.

Among the most frequent nervous phenomena of chronic alcoholism are disturbances of sleep. Sleep is light, uneasy, and disturbed, difficult to obtain, troubled with dreams, and unrefreshing. More or less complete insomnia is by no means rare. It is more apt to occur, however, after acute exacerbations of alcoholism than in the ordinary chronic condition.

¹ *Klinik des Rückenmarkskrankheiten.*

² *Archives de Physiologie nerve et pathologie*, No. 2, 1884.

³ *Brain*, Jan., 1886.

Hyperæsthesia manifests itself as an increased sensibility to pain, to mere contact, to temperature, and in an exaggeration of the muscular sense. Two general forms may be distinguished—the superficial and deep. The former usually manifests itself by an exaggerated sensibility of the skin, especially along the course of the superficial nerves and at their points of emergence from the deeper structures. The latter consists in a more or less intense sensation of pain, often diffuse, sometimes almost unbearable, and associated with a sensation of heat or cold, which is most commonly experienced in the lower extremities. It is often referred by the patient to the deeper muscles or to the bones and joints, and is increased by movement or pressure.

Anæsthesia is a much more common occurrence. It is usually developed during the later period of chronic alcoholism, and may implicate the skin, the mucous tissues, or the deeper structures. It presents all degrees from mere impairment to absolute loss of sensation. In the latter case, contact, pain, temperature, and electrical stimulation equally fail to excite sensation. In the deep anæsthesia of alcoholism pressure and electro-muscular sensibility are alike impaired. The muscular sense is also enfeebled or abolished. The regions which are the seat of anæsthesia are, as a rule, of a lower temperature than those in which sensation is normal. The anæsthesia may extend to the conjunctiva, and even to the cornea and to the mucous membrane of the mouth and throat. It has also been observed in the mucous membrane of the genitalia and at the verge of the anus.

Disorders of Motion.—Disorders of motion consist of tremor, subsultus, spasm, convulsions, muscular paresis, and palsies. Tremor is a very frequent phenomenon in chronic alcoholism. It consists generally of a series of rapid rhythmical movements. Sometimes the extent of the movement is increased and their rhythm irregular. They are then choreiform. The tremor may be continuous; much more frequently it only appears in the morning. The subject has then some difficulty in dressing himself, particularly in buttoning his clothing, in shaving himself, and in raising a cup to his lips. This symptom commonly ceases after the ingestion of a certain quantity of alcohol, only to return on the following morning or after a considerable period of abstinence. Voluntary movements intensify the tremor. It most commonly affects the upper extremities, next in frequency the muscles of the face, and finally the lower extremities. In rare cases it affects the muscles of the whole body. Alcoholic tremor affecting the hands and arms renders the subject awkward and interferes with his ability to work; affecting the lower extremities, it gives rise to an embarrassing, irregular gait; affecting the lips and tongue, it produces hesitation of speech or stammering, and when it is of a high degree articulation may be so imperfect that conversation is impossible; affecting the muscles of the eyes, it gives rise to nystagmus. Tremor is not infrequently associated with subsultus tendinum, spasmodic contractions, and cramps. These phenomena are usually localized, and affect by preference the muscles of the face and those of the lower extremities.

Loss of muscular power, which may pass, little by little, into complete palsy, also occurs. It is, however, neither constant nor proportionate to the gravity of the case in other respects. Whilst, as a rule, it is developed insidiously, it occasionally shows itself with suddenness. In the latter

case it is usually preceded by some acute complication, and may disappear as quickly as it came. At first it is a mere feebleness, which, beginning in the fingers, extends to the hands and arms. It may after a time manifest itself in the feet. More or less muscular paresis is invariably associated with the tremor above described.
